CONTENTS

JULY

EDITORIAL: Multiple organ failure: from basic science to prevention
J. Bion and L. Strunin

MULTIPLE ORGAN FAILURE: FROM BASIC SCIENCE TO PREVENTION

Mechanisms of cell injury and death 3
J. P. Cobb, R. S. Hotchkiss, I. E. Karl and T. G. Buchman

The immuno-inflammatory cascade 11
H. F. Galley and N. R. Webster

Disturbance of leucocyte circulation and adhesion to the endothelium as factors in circulatory pathology 17
D. H. Adams and G. B. Nash

Molecular mechanisms of drug metabolism in the critically ill 32
G. R. Park

Determinants of splanchnic blood flow 50
J. Takala

Splanchnic ischaemia/reperfusion and multiple organ failure 59
W. L. Biffl and E. E. Moore

Determinants of intestinal barrier failure in critical illness 71
J. S. Aranow and M. P. Fink

Mechanisms of acute renal failure 82
C. J. Lote, L. Harper and C. O. S. Savage

Fulminant and late onset hepatic failure 90
A. E. S. Gimson

New approaches to acute lung injury 99
L. M. Bigatello and W. M. Zapol

Sepsis and cytokines: current status 110
T. S. Blackwell and J. W. Christman

Nutrition and immunonutrition 118
M. J. O'Leary and J. H. Coakley

CORRESPONDENCE

Pre-emptive analgesia with NSAID—what does it achieve? 128

Cytokine balance and immunosuppressive changes at cardiac surgery 129

Perioperative changes in α_1-acid glycoprotein concentrations 130

CBF in adults using near infrared spectroscopy (NIRS): potential for bedside measurement 131

Hypercoagulability induced by crystalloids 132

BOOK REVIEWS

Fibreoptic Guided Tracheal Intubation—A Practical Approach 133

Clinical Scenarios in Anaesthesia 133

The Cambridge Dictionary of Statistics in the Medical Sciences 133

The Massachusetts General Hospital Hand Book of Pain Management 134

Clinical Anaesthesiology—International Practice and Research—Obstetric Anaesthesia 134

Low Flow Anaesthesia 134

Total Burn Care 135

AUGUST

EDITORIAL: Transoesophageal echocardiography in anaesthesia and intensive care 137
J. N. Townend and P. Hutton

CLINICAL INVESTIGATIONS

Single bolus compared with a fractionated dose injection technique of bupivacaine for extradural Caesarean section: effect on uteroplacental and fetal haemodynamic state 140
J. Karinen, L. Mäkäräinen, S. Alahuhta, R. Jouppila and P. Jouppila

Spinal anaesthesia with 0.25% hyperbaric bupivacaine for Caesarean section: effects of volume 145
C. J. Chung, S. H. Bae, K. Y. Chae and Y. J. Chin

Spinal anaesthesia for Caesarean section: effect of Sprotte needle orientation 150
K. S. James, S. M. Stott, E. M. McGrady, F. J. Pearsall, W. T. Frame and D. Russell

[illegible] anatomy within the vertebral canal in pregnant [illegible] 153
[illegible]irabayashi, R. Shimizu, H. Fukuda, K. Saitoh and T. Igarashi

Thrombelastography changes in pre-eclampsia and eclampsia 157
C. E. P. Orlikowski, D. A. Rocke, W. B. Murray, E. Gouws, J. Moodley, D. G. Kenoyer and S. Byrne

Alfentanil-mediated analgesia during propofol injection: no evidence for a peripheral action 162
I. J. Wrench, K. J. Girling and G. J. Hobbs

Psychophysical and electrophysiological responses to experimental pain may be influenced by sedation: comparison of the effects of a hypnotic (propofol) and an analgesic (alfentanil) 165
S. Petersen-Felix, L. Arendt-Nielsen, P. Bak, M. Fischer and A. M. Zbinden

Quantitative EEG in assessment of anaesthetic depth: comparative study of methodology 172
C. E. Thomsen and P. F. Prior

Spectral edge frequency of the electroencephalogram to monitor "depth" of anaesthesia with isoflurane or propofol 179
D. Schwender, M. Daunderer, S. Mulzer, S. Klasing, U. Finsterer and K. Peter

The reinforced laryngeal mask airway for dento-alveolar surgery 185
A. C. Quinn, A. Samaan, E. M. McAteer, E. Moss and M. Vucevic

Isoflurane waste gas exposure during general anaesthesia: the laryngeal mask compared with tracheal intubation 189
K. H. Hoerauf, C. Koller, W. Jakob, K. Taeger and J. Hobbhahn

Ventilatory effects of eltanolone during induction of anaesthesia: comparison with propofol and thiopentone 194
H. J. Spens and G. B. Drummond

Effect of anaesthesia on lung function in children with asthma 200
H. A. May, R. L. Smyth, H. C. Romer, P. H. Martin, A. R. Bowhay and D. P. Heaf

Ketamine and norketamine plasma concentrations after i.v., nasal and rectal administration in children 203
J.-M. Malinovsky, F. Servin, A. Cozian, J.-Y. Lepage and M. Pinaud

Determinants of duration of ICU stay after coronary artery bypass graft surgery 208
A. Michalopoulos, G. Tzelepis, G. Pavlides, J. Kriaras, U. Dafni and S. Geroulanos

Comparison of propofol and a propofol–methohexitone mixture for induction of day-case anaesthesia 213
N. Thompson and G. S. Robertson

ASA classification and perioperative variables as predictors of postoperative outcome 217
U. Wolters, T. Wolf, H. Stützer and T. Schröder

Time course of increased haemodilution in hypotension induced by extradural anaesthesia 223
D. Drobin and R. G. Hahn

LABORATORY INVESTIGATIONS

Combination of inhaled nitric oxide with i.v. nitroglycerin or with a prostacyclin analogue in the treatment of experimental pulmonary hypertension 227
L. J. Van Obbergh, M. Charbonneau and G. Blaise

Role of prostaglandins and nitric oxide on halothane-induced arteriolar dilatation in rat diaphragm 232
V. de Larminat, J. Boczkowski, B. Dureuil, E. Vicaut, R. Farinotti, M. Aubier and J.-M. Desmonts

Ketamine inhibits nitric oxide production in mouse-activated macrophage-like cells 238
M. Shimaoka, T. Iida, A. Ohara, N. Taenaka, T. Mashimo, T. Honda and I. Yoshiya

Potentiation of local lignocaine-induced sensory block by calcium channel blockers in rats 243
H. Iwasaki, H. Ohmori, K. Omote, M. Kawamata, S. Sumita, M. Yamauchi and A. Namiki

I.v. anaesthetic agents inhibit dihydropyridine binding to L-type voltage-sensitive Ca^{2+} channels in rat cerebrocortical membranes 248
K. Hirota and D. G. Lambert

Is inhibition of dopamine uptake relevant to the hypnotic action of i.v. anaesthetics? ... 254
H. Keita, J. B. Lecharny, D. Henzel, J. M. Desmonts and J. Mantz

Myocardial extraction of bupivacaine in anaesthetized sheep and by hearts of sheep and rats *in vitro* ... 257
H. Foth, T. Schröder, B. Kraus, J. P. Hering, F. M. B. Ensink and G. Hellige

SHORT COMMUNICATIONS

Nitrous oxide produces a non-linear reduction in thiopentone requirements ... 265
T. Katoh and K. Ikeda

Evaluation of two warming systems after cardiopulmonary bypass ... 268
E. L. Janke, S. N. Pilkington and D. C. Smith

Calcium homeostasis during i.v. infusion of 1.5% glycine in anaesthetized pigs ... 271
D. Chassard, K. Berrada, J. P. Tournadre and P. Boulétreau

CASE REPORTS

Cardiac arrest after Caesarean section under subarachnoid block ... 274
T. J. Scull and F. Carli

Severe systemic cholesterol embolization after open heart surgery ... 277
V. Piriou, J.-Ph. Claudel, O. Bastien, S. Ross and J.-J. Lehot

ABSTRACTS

Proceedings of the Anaesthetic Research Society, Nottingham Meeting, March 28–29, 1996 ... 281P

CORRESPONDENCE

CSF progesterone and spread of subarachnoid anaesthesia in pregnancy ... 293
Sevoflurane ... 294
Removal of extradural catheters ... 295
Optimal intracuff pressures with the laryngeal mask ... 295
Prevention of cardiovascular response to tracheal intubation ... 296
Tea-total ... 297
Analgesia: dose-effect or pre-emptive effect? ... 297
Convective warming after CABG ... 298
Adequate general anaesthesia—what are we trying to achieve? ... 299
Spinal anaesthesia for Caesarean section ... 301

BOOK REVIEWS

Regional Anesthesia: An Illustrated Procedural Guide, 2nd Edn ... 303
ABC of Brainstem Death, 2nd Edn ... 303
Recent Advances in Anaesthesia and Analgesia–19 ... 303

SEPTEMBER

EDITORIALS:

I: Complications of hysteroscopic treatments of menorrhagia ... 305
K.M. Williamson, M.C. Mushambi

II What future is there for predicting difficult intubation? ... 309
P. Charters

CLINICAL INVESTIGATIONS

Sternomental distance as the sole predictor of difficult laryngoscopy in obstetric anaesthesia ... 312
S. A. L. Ramadhani, L. A. Mohamed, D.A. Rocke and E. Gouws

Respiratory mechanics after abdominal surgery measured with continuous analysis of pressure, flow and volume signals ... 317
A. F. Nimmo and G. B. Drummond

Thoracic impedance used for measuring chest wall movement in postoperative patients ... 327
G. B. Drummond, A. F. Nimmo and R. A. Elton

Preoxygenation in children using expired oxygraphy ... 333
P. J. Butler, H. M. Munro and M. B. Kenny

Intubating conditions and time course of rocuronium-induced neuromuscular block in children ... 335
T. Fuchs-Buder and E. Tassonyi

Influence of induction technique on intubating conditions after rocuronium in adults: comparison with rapid-sequence induction using thiopentone and suxamethonium ... 339
H.J. Sparr, S. Giesinger, H. Ulmer, M. Hollenstein-Zacke and T.J. Luger

Spinal anaesthesia with 0.5% hyperbaric bupivacaine in elderly patients: effect of site of injection on spread of analgesia ... 343
B. Th. Veering, P. M. Ter Riet, A. G. L. Burm, R. Stienstra and J. W. van Kleef

Inflammatory changes after extradural anaesthesia may affect the spread of local anaesthetic within the extradural space ... 347
T. Igarashi, Y. Hirabayashi, R. Shimizu, H. Mitsuhata, K. Saitoh, H. Fukuda, A. Konishi and H. Asahara

Acid–base state of cerebrospinal fluid during pregnancy and its effect on spread of spinal anaesthesia ... 352
Y. Hirabayashi, R. Shimizu, K. Saitoh, H. Fukuda and T. Igarashi

Nausea and vomiting after cardiac surgery ... 356
C.R. Grebenik and C. Allman

Cardiopulmonary bypass-induced changes in plasma concentrations of propofol and in auditory evoked potentials ... 360
E. Hammarén, A. Yli-Hankala, P. H. Rosenberg and M. Hynynen

On-line estimation of left ventricular stroke volume using transoesophageal echocardiography and acoustic quantification ... 365
C.-A. Greim, N. Roewer, G. Laux and J. Schulte am Esch

Patient-controlled sedation for cataract surgery using peribulbar block ... 370
C. K. Pac-Soo, S. Deacock, G. Lockwood, C. Carr and J. G. Whitwam

LABORATORY INVESTIGATIONS

Synergistic interactions between midazolam and alfentanil in isolated neonatal rat spinal cord ... 375
J. Feng and J. J. Kendig

Differential effects of ketamine and pentobarbitone on acetylcholine release from the rat hippocampus and striatum ... 381
K. Sato, J. Wu, T. Kikuchi, Y. Wang, I. Watanabe and F. Okumura

I.v. anaesthetic agents do not interact with the verapamil binding site on L-type voltage-sensitive Ca^{2+} channels ... 385
K. Hirota and D. G. Lambert

Flow cytometry evaluation of the *in vitro* influence of four i.v. anaesthetics on respiratory burst of neutrophils ... 387
J. Heine, M. Leuwer, D. Scheinichen, L. Arseniev, K. Jaeger and S. Piepenbrock

Atrioventricular conduction during adenosine-induced hypotension in dogs anaesthetized with sevoflurane ... 393
R. Ishii, S. Akazawa, R. Shimizu, Y. Nakaigawa, S. Ikeno and R. Yamato

Effects of fentanyl, nitrous oxide, or both, on baroreceptor reflex regulation in the cat ... 399
Ö. Lennander, B-Å. Henriksson, J. Martner and B. Biber

Effect of sevoflurane anaesthesia on plasma concentrations of glutathione S-transferase ... 404
D. C. Ray, R. Bomont, A. Mizushima, T. Kugimiya, A. Forbes Howie and G. J. Beckett

Normovolaemic haemodilution attenuates cardiac depression induced by sodium bicarbonate in canine metabolic acidosis ... 408
M. Tanaka, T. Nishikawa and T. Mizutani

Inhalation of a nitric oxide synthase inhibitor to a hypoxic or collapsed lung lobe in anaesthetized pigs: effects on pulmonary blood flow distribution ... 413
F. Fredén, J. E. Berglund, A. Reber, M. Högman and G. Hedenstierna

SHORT COMMUNICATIONS

Influence of patient position on withdrawal forces during removal of lumbar extradural catheters ... 419
G. N. Morris, B. B. Warren, E. W. Hanson, F. J. Mazzeo and D. J. DiBenedetto

Effect of oral antihistamine premedication on mivacurium-induced histamine release and side effects 421
A. Doenicke, J. Moss, W. Lorenz, M. Mayer, J. Rau, A. Jedrzejewski and P. Ostwald

Edrophonium and human plasma cholinesterase combination for antagonism of mivacurium-induced neuromuscular block 424
M. Naguib, A. H. Samarkandi, H. S. Bakhamees, A. Turkistani and S. W. Alharby

Beneficial effects of dexmedetomidine on ischaemic myocardium of anaesthetized dogs 427
P. M. H. J. Roekaerts, F. W. Prinzen and S. De Lange

CASE REPORT

An iatrogenic arterial foreign body 430
U. S. Shah, R. Downing and I. Davis

EQUIPMENT

An effective method of scavenging nitric oxide 432
S. Squire, R. Kightley and A. J. Petros

CORRESPONDENCE

The care of patients and transport by air 435
Effect of naloxone on nitrous oxide analgesia 435
Difficult tracheal intubation 436
Cost of volatile anaesthetic agents 437
Erratum 437

BOOK REVIEWS

Clinical Orthopedic Anesthesia. 438
Clinical Anesthesiology, 2nd Edn. 438
Baillière's Clinical Anaesthesiology: International Practice and Research, vol. 10, No. 1. The Lung in Anaesthesia and Intensive Care. 439
Chemical Warfare Agents. Toxicology and Treatment. 439

OCTOBER

EDITORIAL: Ketamine: its mechanism(s) of action and unusual clinical uses 441
K. Hirota and D. G. Lambert

CLINICAL INVESTIGATIONS

Morphine consumption in patients receiving rectal paracetamol and diclofenac alone and in combination 445
J. E. Montgomery, C. J. Sutherland, I. G. Kestin and J. R. Sneyd

Postoperative pulmonary function after laparoscopic and open cholecystectomy 448
A. J. Karayiannakis, G. G. Makri, A. Mantzioka, D. Karousos and G. Karatzas

Influence of motivation of care providers on the incidence of postoperative hypoxaemia in the recovery room 453
A. T. Rheineck-Leyssius, C. J. Kalkman and A. Trouwborst

Extradural clonidine combined with sufentanil and 0.0625% bupivacaine for analgesia in labour 458
D. Chassard, L. Mathon, F. Dailler, F. Golfier, J. P. Tournadre and P. Boulétreau

Antiemetic effect of subhypnotic doses of propofol after thyroidectomy 463
P. Ewalenko, S. Janny, M. Dejonckheere, G. Andry and C. Wyns

Use of a mechanical simulator for training in applying cricoid pressure 468
N. Ashurst, C. C. Rout, D. A. Rocke and E. Gouws

Endotoxaemia and postoperative hypermetabolism in coronary artery bypass surgery: the role of ketanserin 473
H. M. Oudemans-van Straaten, P. G. M. Jansen, H. te Velthuis, Chr. P. Stoutenbeek, D. F. Zandstra, S. J. H. van Deventer, A. Sturk, Ch. R. H. Wildevuur and L. Eijsman

Influence of different volume therapy regimens on regulators of the circulation in the critically ill 480
J. Boldt, M. Mueller, T. Menges, M. Papsdorf and G. Hempelmann

Potency and time course of action of rocuronium during desflurane and isoflurane anaesthesia 488
N. Kumar, R. K. Mirakhur, M. J. J. Symington and G. J. McCarthy

Neuromuscular blocking action of suxamethonium after antagonism of vecuronium by edrophonium, pyridostigmine or neostigmine 492
N. W. Fleming, S. Macres, J. F. Antognini and J. Vengco

Is recovery of neuromuscular transmission complete after the use of neostigmine to antagonize block produced by rocuronium, vecuronium, atracurium and pancuronium? 496
M. J. Baurain, F. Hoton, A. A. d'Hollander and F. R. Cantraine

Chronic carbamazepine therapy does not influence mivacurium-induced neuromuscular block 500
A. Spacek, F. X. Neiger, C. K. Spiss and H. G. Kress

LABORATORY INVESTIGATIONS

Thiobarbiturates suppress depolarization-induced contraction of vascular smooth muscle without suppression of calcium influx 503
R. Kitamura, M. Kakuyama, K. Nakamura, I. Miyawaki and K. Mori

Comparative actions of propofol and thiopentone on cell membranes of isolated guineapig ventricular myocytes 508
F. Sakai, M. Hiraoka and K. Amaha

Dose–response curve for anaesthetics based on the Monod–Wyman–Changeux model 517
T. Iwai, H. Kihara, K. Imaiand and M. Uchida

Visual evoked potentials and nitrous oxide-induced neuronal depression: role for benzodiazepine receptors 522
M. Dzoljic, W. Erdmann and M. R. Dzoljic

Pancuronium increases pulmonary arterial pressure in lung injury 526
H. Du, R. Orii, Y. Yamada, M. Hayashita, N. Kin, K. Suwa and K. Hanaoka

Efficacy of intraoperative heat administration by ventilation with warm humidified gases and an oesophageal warming system 530
E. Beck, M. Langer, P. Di Mauro and P. Prato

Extraction of nitric oxide and nitrogen dioxide from an oxygen carrier using molecular sieve 5A 534
B. B. Poulton, L. Foubert, J. Klinowski, R. D. Latimer, P. R. Knowles and A. Vuylsteke

Sevoflurane degradation to compound A in anaesthesia breathing systems 537
D. D. Cunningham, S. Huang, J. Webster, J. Mayoral and R. W. Grabenkort

SHORT COMMUNICATION

Evaluation of the usefulness of intrathecal bupivacaine infusion for analgesia after hip and knee arthroplasty. 544
L. Niemi, M. Pitkänen, P. Dunkel, E. Laakso and P. H. Rosenberg

CASE REPORTS

Bilateral compartment syndrome complicating prolonged lithotomy position 546
J. Tuckey

Extradural anaesthesia for Caesarean section in a patient with moyamoya disease 550
W. D. Ngan Kee and C. D. Gomersall

Unrecognized "crack" cocaine abuse in pregnancy 553
D. Campbell, M. J. A. Parr and L. E. Shutt

Heparinase-guided thrombelastography in an anticoagulated parturient 556
D. C. Abramson, E. I. Abouleish, E. G. Pivalizza, S. L. Luehr, T. Myers and M. D. Phillips

CORRESPONDENCE

Failed tracheal intubation 559
Perioperative mucosal pH_i in orthotopic liver transplantation 560
Volatile anaesthetics and neuromuscular block 561
Cusum: a statistical method to evaluate competence in practical procedures 562

BOOK REVIEWS

Critical Care: Standards, Audit and Ethics 563
Comprehensive Human Physiology from Cellular Mechanisms to Integration, vols 1 and 2 563
Critical Care of Infants and Children 564
Anaesthesia Review 12 564
Clinical Risk Management 564
Neuromuscular Transmission. Fundamentals of Anaesthesia and Acute Medicine Series 565

Errata 566

NOVEMBER

EDITORIAL: Does anaesthesia have long-term consequences? 569
G. R. Masterson and J. M. Hunter

CLINICAL INVESTIGATIONS

Sleep after laparoscopic cholecystectomy 572
S. Rosenberg-Adamsen, M. Skarbye, G. Wildschiødtz, H. Kehlet and J. Rosenberg

Gasless laparoscopic cholecystectomy: comparison of postoperative recovery with conventional technique 576
A.-M. Koivusalo, I. Kellokumpu and L. Lindgren

Haemodynamic and metabolic response to endovascular repair of infra-renal aortic aneurysms 581
B. R. Baxendale, D. M. Baker, A. Hutchinson, T. A. M. Chuter, P. W. Wenham and B. R. Hopkinson

Comparison of caudal bupivacaine and diamorphine with caudal bupivacaine alone for repair of hypospadias 586
A. A. Kelleher, A. Black, S. Penman and R. Howard

Effect of hypothermia on rectal mucosal perfusion in infants undergoing cardiopulmonary bypass 591
P. D. Booker, D. P. Prosser and R. Franks

Gut mucosal perfusion in neonates undergoing cardiopulmonary bypass 597
P. D. Booker, H. Romer and R. Franks

Effects of dopamine on oxygen consumption and gastric mucosal blood flow during cardiopulmonary bypass in humans 603
W. Karzai, M. Günnicker, G. Scharbert, U. M. Vorgrimler-Karzai and H. -J. Priebe

Effects of rocuronium and vecuronium on intracranial pressure, mean arterial pressure and heart rate in neurosurgical patients 607
W. M. Schramm, K. Strasser, A. Bartunek, H. Gilly and C. K. Spiss

Interactions between suxamethonium and mivacurium or atracurium 612
K. S. Kim, D. J. Na and S. U. Chon

Midlatency auditory evoked potentials as indicators of perceptual processing during general anaesthesia 617
N. A. M. de Beer, J. C. van Hooff, C. H. M. Brunia, P. J. M. Cluitmans, H. H. M. Korsten and J. E. W. Beneken

Effect of racemic mixture and the (S+)-isomer of ketamine on temporal and spatial summation of pain 625
L. Arendt-Nielsen, J. Nielsen, S. Petersen-Felix, T. W. Schnider and A. M. Zbinden

Normal saline i.v. fluid load decreases uterine activity in active labour 632
T. G. Cheek, P. Samuels, F. Miller, M. Tobin and B. B. Gutsche

Fuzzy logic control of mechanical ventilation during anaesthesia 636
J. Schäublin, M. Derighetti, P. Feigenwinter, S. Petersen-Felix and A. M. Zbinden

An oral sodium citrate–citric acid non-particulate buffer in humans 642
J. J. Hauptfleisch and K. A. Payne

LABORATORY INVESTIGATIONS

Effects of local anaesthetics on carrageenan-evoked inflammatory nociceptive processing in the rat 645
J. Buritova, D. Fletcher, P. Honoré and J.-M. Besson

Myocardial effects of eltanolone in hamsters with hypertrophic cardiomyopathy 653
P. Ruel, J.-L. Hanouz, B. Riou, Y. Lecarpentier and P. Coriat

Comparison of the effects of controlled ventilation with 100% oxygen, 50% oxygen in nitrogen, and 50% oxygen in nitrous oxide on responses to venour air embolism in pigs 658
J. Kyttä, P. Tanskanen and T. Randell

SHORT COMMUNICATION

Use of the fibrescope–video camera system for difficult tracheal intubation 662
K. Aoyama, I. Takenaka, T. Sata and A. Shigematsu

CASE REPORTS

General anaesthesia for Caesarean section in a parturient with Noonan's syndrome 665
H. A. McLure and S. M. Yentis

Use of rocuronium in a pregnant patient with an open eye injury, receiving magnesium medication, for preterm labour 669
R. R. Gaiser and E. H. Seem

Isoflurane for sedation in a case of congenital myasthenia gravis 672
C. McBeth and T. G. L. Watkins

Orthotopic liver transplantation in two patients with hypertrophic obstructive cardiomyopathy 675
I. D. Harley, E. F. Jones, G. Liu, P. R. McCall and P. L. McNicol

COMMENTARY

Permissive hypercapnia and gas exchange in lungs with high $\dot{Q}s/\dot{Q}t$: a mathematical model 678
C. J. Joyce and K. G. Hickling

ABSTRACTS

Proceedings of the Anaesthetic Research Society, Birmingham Meeting, July 11–12, 1996 .... 684P

CORRESPONDENCE

Volumetric analysis of aeration in the lungs during general anaesthesia 697
Failed intubation during obstetric anaesthesia 698
The intensive care unit cost of surviving and dying 698
Aortic stent surgery 699
A complication of intra-arterial shunting during carotid endarterectomy 699
Transoesophageal echocardiography in anaesthesia and intensive care 700
Haemodilution induces a hypercoagulable state 700

Erratum 701

DECEMBER

EDITORIALS:

I Ether anaesthesia comes to London. December 1846 ... 705
A. A. Spence

II Is it always necessary to antagonize residual neuromuscular block? Do children differ from adults? ... 707
J. M. Hunter

CLINICAL INVESTIGATIONS

Dose–response relationships for neostigmine antagonism of rocuronium-induced neuromuscular block in children and adults ... 710
M. Abdulatif, H. Mowafi, Al-Ghamdi and M. El-Sanabary

Comparison of the effects of mivacurium on the diaphragm and geniohyoid muscles ... 716
G. d'Honneur, V. Slavov, J.-C. Merle, K. Kirov, J.-M. Rimaniol, L. Sperry and P. Duvaldestin

Concentration-related effects of propofol on the auditory evoked response ... 720
M. A. Tooley, G. L. Greenslade and C. Prys-Roberts

Comparison of patient-controlled sedation with either methohexitone or propofol ... 727
S. K. Hamid, N. McCann, L. McArdle and A. J. Asbury

Local anaesthesia to the airway reduces sedation requirements in patients undergoing artificial ventilation ... 731
A. Mallick, S. N. Smith and A. R. Bodenham

Comparative effects of thiopentone and propofol on respiratory resistance after tracheal intubation ... 735
R. S. C. Wu, K. C. Wu, D. C. W. Sum and M. J. Bishop

Propofol or halothane anaesthesia for children with asthma: effects on respiratory mechanics ... 739
W. Habre, I. Matsumoto and P. D. Sly

Hepatocellular integrity during and after isoflurane and halothane anaesthesia in surgical patients ... 744
P. Tiainen and P. H. Rosenberg

Standardization of non-invasive impedance cardiography for assessment of stroke volume: comparison with thermodilution ... 748
H. H. Woltjer, H. J. Bogaard, G. J. Scheffer, H. I. van der Spoel, M. A. J. M. Huybregts and P. M. J. M. de Vries

Lack of specific renal haemodynamic effects of different doses of dopamine after infrarenal aortic surgery ... 753
A. R. J. Girbes, A. G. Lieverse, A. J. Smit, D. J. van Veldhuisen, J. H. Zwaveling, S. Meijer and W. D. Reitsma

LABORATORY INVESTIGATIONS

Antinociception by intrathecal midazolam involves endogenous neurotransmitters acting at spinal cord delta opioid receptors ... 758
C. S. Goodchild, Z. Guo, A. Musgreave and J. P. Gent

A model of the first pass passage of drugs from i.v. injection site to the heart—parameter estimates for lignocaine in the sheep ... 764
R. N. Upton

Measurement of cardiac output by transoesophageal Doppler echocardiography in anaesthetized horses: comparison with thermodilution ... 773
L. E. Young, K. J. Blissitt, D. H. Bartram, R. E. Clutton, V. Molony and R. S. Jones

Effect of halothane, isoflurane and desflurane on lower oesophageal sphincter tone ... 781
D. Chassard, J. P. Tournadre, K. R. Berrada, B. Bryssine and P. Bouletreau

SHORT COMMUNICATIONS

Distinguishing cerebrospinal fluid from saline used to identify the extradural space ... 784
B. A. Z. El-Behesy, D. James, K. F. Koh, N. Hirsche and S. M. Yentis

Use of a pneumatic tourniquet induces changes in central temperature ... 786
J.-P. Estebe, A. Le Naoures, Y. Malledant and C. Ecoffey

CASE REPORTS

A modification of sub-mental intubation ... 789
J. D. Green and U. J. Moore

EDITORIAL

Multiple organ failure: from basic science to prevention

Multiple organ failure is a modern epidemic, first described in the mid-1970s [1, 2]. This syndrome of multiple organ failure is both the *raison d'etre* and the consequence of skilled intensive care medicine, created by our success in providing sophisticated organ system support to patients who, a few years ago, would have died rapidly from their acute disease. Although many of these patients now survive, the cost of success is high. The mortality from multiple organ failure increases with the number and duration of failing organs [3], and as it costs twice as much to die in an intensive care unit as it does to survive [4], the resources required to generate a survivor are considerable. For those patients destined to die, prognostic uncertainty encourages protracted organ system support [5], with the result that death is merely deferred at greater expense. The challenge for intensive care medicine is to develop cost-effective methods for improving survival rates, while reducing expenditure on those who ultimately will die. Efforts to identify patients who cannot benefit from continued support have not been successful, primarily because group probabilities cannot be used to predict outcome for individual patients. Similarly, the biotechnological approach to sepsis has consumed a considerable amount of venture capital with, as yet, little evident return on the investment. A different approach is needed which links the pathogenesis of multiple organ failure with its prevention, and with techniques to restore cellular and organ function.

This postgraduate issue of the journal is a joint venture between the Intensive Care Society and the *British Journal of Anaesthesia*. The reviews consider the mechanisms by which organ failures occur and methods for limiting cellular damage and restoring lost function. While the factors which precipitate cell injury and organ failure are amenable to relatively simple preventative interventions, once damage has occurred the process becomes increasingly complex and self-sustaining. Natural defence systems may become pathologically hyperactive, or suppressed at different stages of critical illness, making it difficult to target therapies directed at the immuno-inflammatory cascade with any degree of accuracy or safety. The prevention of critical illness must become a priority, but to do so successfully depends on developing better systems for identifying patients at risk [6], as well as understanding the pathophysiology of multiple organ failure. Considerable research investment is needed to assess the factors which determine susceptibility to, and recovery from, this syndrome.

In this postgraduate issue the reader will find views on the present state of knowledge with regard to cells, the gastrointestinal tract, nutrition, infection, the lung, kidney and liver and their place in multiple organ failure. Current therapy is outlined and there are clear indicators for future research. The busy clinician may be forgiven for wondering why there is little mention of the day-to-day problems which beset every intensive care unit; the "real world–coal face" issues of apparent lack of resources, staffing, equipment, etc. These are important matters, but result from the unrelenting and, to a great extent, unregulated demand for intensive care. This demand cannot be met by spending more money alone, as was demonstrated in the USA in a recent budget year where 1% of its gross domestic product was spent on intensive care medicine. The return on this enormous investment was difficult to assess and although improvement in outcome was demonstrated in some areas, continued spending at the 1% level could not be justified. In the United Kingdom there is a shortage of intensive care beds brought recently to public attention by a number of patients ferried around the country seeking a bed under the full glare of the media spotlight. These events led to a Government commitment to consider more resources for intensive care. Nevertheless, it is unlikely that these will be sufficient to satisfy the current demand; indeed the American experience suggests that even unlimited resources would not be cost-effective unless carefully targeted. This issue of the journal should, at the very least, be helpful for the clinician in deciding where scarce resources should best be spent as they become available.

As intensive care medicine progresses towards independent specialty status, this is perhaps an opportune moment to acknowledge the substantial contribution which anaesthesia has made both to the service and science of intensive care medicine. We hope that the good relationships which exist between intensive care medicine and all the other major disciplines will foster further collaborative activities of this type, with a particular emphasis on drawing together clinical research with the basic sciences.

Mechanisms of cell injury and death

J. P. Cobb, R. S. Hotchkiss, I. E. Karl and T. G. Buchman

Control of the rate of cell death relative to the rate of cell division maintains organ integrity and physiological homeostasis. Cell death is valuable for the organism because it removes terminally injured or unwanted cells that utilize valuable substrates and nutrients. Likewise, cell death also has value for the species, as it provides a mechanism for eliminating terminally injured individuals who consume necessary societal resources or harbour toxic pathogens. Recent advances in cellular biology have contributed substantially to our understanding of the processes of cell injury and death, and have provided the molecular tools necessary to control it. This paper reviews cell injury and adaptation; mechanisms of cell death; the roles of cell injury and death in the pathophysiology of organ dysfunction; and implications for prevention and therapy of multiple organ dysfunction syndrome (MODS).

Cell injury and adaptation

Cell injury occurs as a result of physical, chemical or biological insults or as a result of vital substrate deficiency (table 1). The cellular response to these injuries is adaptive, designed to restore homeostasis and protect the cell from further injury. Although characteristic changes in gene transcription occur, it is not the relative amount but the pattern of transcription that changes, with emphasis directed towards transcription of "vital" genes. The responses induced by cellular injury fall into four main patterns: the ischaemic/anoxic, oxidative, heat shock and acute phase responses. These are reviewed briefly below.

ISCHAEMIC/ANOXIC STRESS RESPONSE [13]

Because of the unusual high efficiency of the cardiopulmonary system to transport oxygen, cells in higher animals have not developed elaborate cellular pathways to adapt to hypoxia and are thus relatively sensitive to ischaemia [13, 18]. As a consequence, lack of oxygen dramatically increases the need for anaerobic glycolysis to maintain intracellular ATP reserves. The associated changes in gene expression include decreased total protein synthesis, induction of hypoxia-associated proteins (e.g. glyceraldehyde-3-phosphate dehydrogenase, a glycolytic enzyme), induction of the heat shock response (see below), and induction of glucose-regulated proteins. If these changes are inadequate to prevent ATP depletion, membrane ion pumps fail and membrane integrity is lost. Increased intracellular Ca^{2+} occurs and a variety of degradative processes are initiated, leading to cytoplasmic swelling and eventual cell death.

OXIDATIVE STRESS RESPONSE [9]

Agents that provoke oxidative injury include products of oxidative metabolism (especially from the mitochondria) and those released from activated phagocytes. Collectively, they are called *reactive oxygen species* (ROS), and include superoxide, hydrogen peroxide, hydroxyl radical (the generation of which depends on availability of ferrous ion and superoxide) and nitric oxide. Iron, which is essential for DNA synthesis and oxidative metabolism, also catalyses the Fenton and Haber-Weiss reactions, converting superoxide to molecular oxygen and hydrogen peroxide to the hydroxyl radical. Under normal conditions, free iron is compartmentalized by the protein ferritin, which "protects" the cell by keeping iron in a non-reactive crystallized core as ferric ion (Fe^{3+}). The results of the oxidative reactions of ROS include de-energization of mitochondria and loss of energy stores, peroxidation and disruption of lipid membranes, and direct DNA damage.

The adaptive response of the cell to oxidative stress includes both enzymatic and non-enzymatic capacities and induction of oxidative stress response proteins [9]. Superoxide dismutase reduces superoxide to molecular oxygen and hydrogen peroxide; catalase catalyses the conversion of this hydrogen peroxide to oxygen and water. Reduced glutathione (which reacts with hydrogen peroxide in the presence of glutathione peroxidase to form water and oxidized glutathione), vitamin C and vitamin E constitute the

major intracellular reducing (non-enzymatic) agents. Several proteins are induced under oxidative stress, the most important of which may be metallothionein, which binds not only heavy metals but also ROS via the free sulphydryl groups of its many cysteine residues. ROS also activate the transcriptional factors AP-1 and NFκB, both of which promote transcription of cytokines and have been associated with induction of apoptotic cell death (see below). If these adaptive responses are inadequate to prevent depletion of cellular glutathione, then cell protein thiol groups become the remaining reducing agents, leading to loss of critical enzymatic function and cell death.

HEAT SHOCK RESPONSE [10, 20]

The highly conserved cellular response to heat, known as the heat shock response, is associated with induction of *heat shock proteins* (HSP). The most extensively studied are the HSP 70 family, which includes stress-induced HSP 72. Interestingly, HSP also are induced by a variety of other cellular insults, including ischaemia/reperfusion, oxidative stress, exposure to heavy metals (e.g. arsenite) and infection. For this reason, the heat shock response is called simply the "stress response", and HSP are known as "stress proteins". Control of HSP transcription is mediated by heat shock element activation in the heat shock protein promoter region. HSP aid in the proper folding of newly translated proteins, and are referred to as "molecular chaperones". Increased production of HSP is believed to provide an adaptive advantage to stressed cells by increasing the fidelity of protein synthesis and aiding refolding of damaged or denatured proteins.

ACUTE PHASE RESPONSE [26]

Although "acute phase response" can refer to the response of any tissue to injury, its use is commonly restricted to the dramatic change in the pattern of hepatocyte protein synthesis. The most important stimuli are interleukin 1 (IL-1), tumour necrosis factor (TNF), and IL-6, products of macrophage/monocyte activation. The hepatocyte response to these cytokines is an outpouring of plasma proteins that function to maintain the homeostasis of the organism. They include C-reactive protein, fibrinogen, complement, the metal binding proteins haptoglobin and ferritin, and plasminogen activator inhibitor and many others. The acute phase response (activation) of endothelial cells includes increased surface expression of adhesion, selectin and integrin molecules that facilitate leucocyte adhesion and release of IL-1, IL-6, IL-8 and platelet activating factor (PAF).

Mechanisms of cell death

If the genetic and metabolic adaptive responses described above are inadequate for a given injury, the cell will die. Increased interest in the mechanisms responsible for cell death, however, has made it clear that morphological classification of cell death requires revision. At least two types of cell death have been described. In the first, cell damage is manifested by cytoplasmic swelling, plasma membrane blebbing, dilation of the endoplasmic reticulum and mitochondria, dissolution of chromatin and, finally, interruption of membrane integrity. The other, less frequently observed type of cell death was described by Kerr [16] and called *shrinkage necrosis*. It is manifested by cytoplasmic shrinkage, larger plasma membrane buds and nuclear chromatin condensation. Both types of cell death result in the generation of necrotic debris that is engulfed by phagocytic cells.

TERMINOLOGY

The morphological changes described above are not restrictive. Nuclear condensation and mitochondrial swelling, for example, have been observed in both swelling and shrinkage types of cell death. There is also clear evidence of significant overlap between them at the molecular level (see below) [11, 14, 18]. Moreover, there is considerable imprecision in the literature regarding the terminology of cell death. Historically, *necrosis* has been the term used to refer to cell death in general. The term *apoptosis* (coined by Kerr, Wyllie, and Currie from the Greek word meaning "dropping off", as in leaves dropping from a tree [17]) is now used specifically to describe death manifested by cell shrinkage. Apoptosis is responsible for the ordered, normal cell death of intestinal epithelial cells and blood neutrophils.

Programmed cell death, which refers to the ordered death of cells during embryogenesis, however, is also characterized by cell shrinkage. Apoptosis and programmed cell death are frequently, but incorrectly, used interchangeably. The question of what to call non-apoptotic cell death has been problematic. *Necrosis*, a leading contender, is also used to refer to the process of removal of the cellular remains of apoptosis (so-called "post-apoptotic necrosis" [18]) [11, 32]. This degree of imprecision led Farber recently to remark that "there is no field of basic cell biology and cell pathology that is more confusing and unintelligible than is the area of *apoptosis versus necrosis*" [11]. Consequently, several

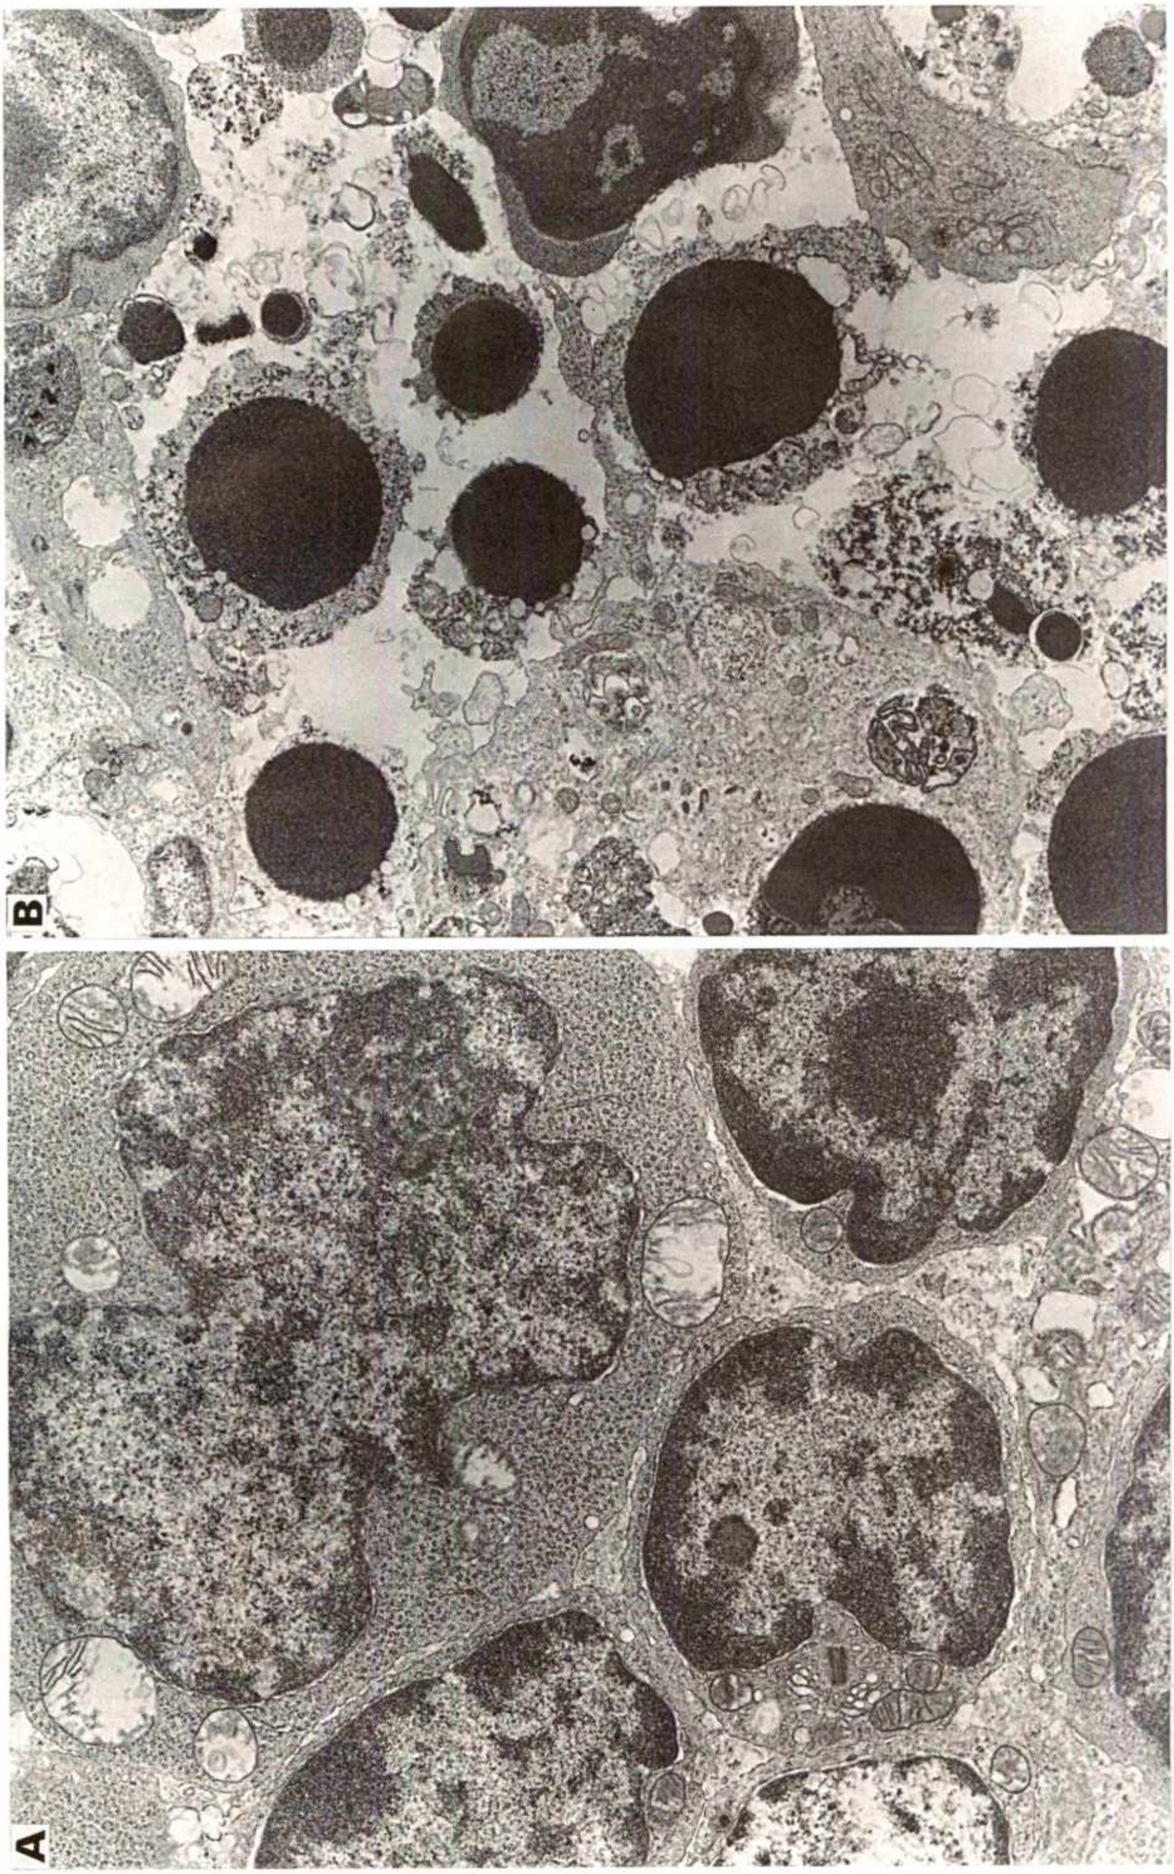

Figure 1 Electron micrographs of murine thymocytes from normal (A, sham laparotomy) and septic (B, caecal ligation and puncture) mice. Note the differences in the pattern and distribution of chromatin. Compared with controls (A), thymocytes from septic animals (B) demonstrate nuclear condensation and cell shrinkage, consistent with apoptosis.

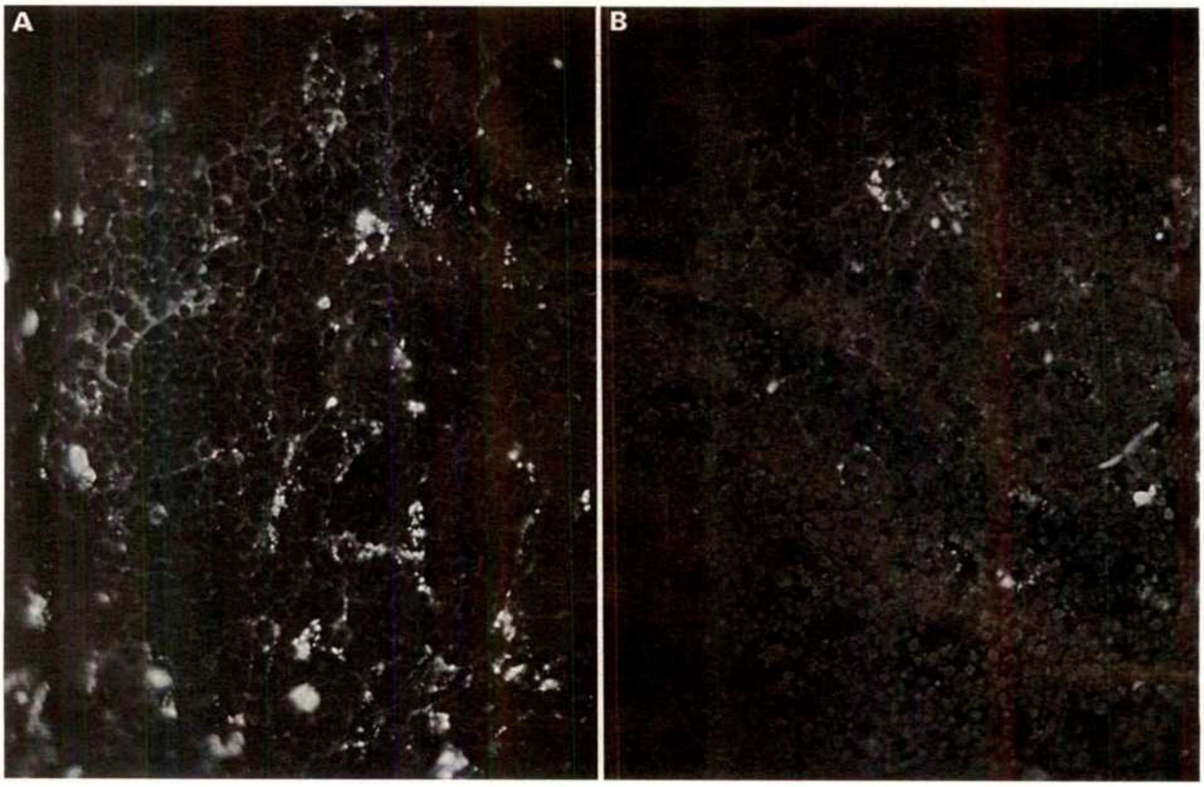

Figure 2 Micrographs (×360 magnification) of murine thymocytes from normal (A, sham laparotomy) and septic (B, caecal ligation and puncture) mice photographed using the fluorescent TUNEL (terminal deoxynucleotidyl transferase-mediated dUTP nick end-labelling) technique. Cells are permeabilized and treated with fluorescein labelled dUTP and terminal deoxynucleotide transferase. Note that in the control mice, all nuclei appear dark (A). In contrast, nuclei of septic mice (B) are fluorescent, consistent with DNA strand breaks and apoptosis.

authors have reviewed this subject in an attempt to standardize terminology and separate the process from the morphology of cell death [11, 14, 15, 18].

PROCESS OF CELL DEATH

From a pathological standpoint, it is important to distinguish between the process of cells dying *per se* from the changes that occur in cells after death [11, 18]. Majno and Joris [18] have characterized the *process* of cell death as (1) cell death by ischaemia, (2) cell death by accident, or (3) cell death by suicide. Accidental cell death is used to describe death as a result of an external agent or toxin. Both cell death secondary to ischaemia and accident are usually characterized morphologically by cell swelling. In this type of cell death, interference with ATP generation secondary to hypoxia or toxin-induced increases in plasma membrane permeability produce membrane failure. Reversible consequences of injury include cytoplasmic blebbing, nuclear chromatin condensation, dilation of the endoplasmic reticulum, condensation then swelling of mitochondria and activation of stress response genetic programmes (described above). Continued injury results in interruptions of membrane integrity, dissolution of chromatin, and calcifications within mitochondria, all of which are signs of irreversible cell injury and death. Majno and Joris [18] have suggested the term *oncosis*, from the Greek word meaning "swelling", for this type of cell death. *Necrosis* is the morphological term used for the cellular debris remaining after either oncosis or apoptosis [18].

Death by suicide refers to the process of cell death in which injury activates a highly conserved programme of "suicide" genes that engineer death of the cell. This process typically results morphologically in apoptosis. Interest in cell death by suicide (apoptosis) has gained considerable momentum recently as the disorders associated with apoptotic cell death have expanded to include cancer, autoimmunity, inflammation, infection, AIDS, neurodegeneration and myelodysplasia [31]. The molecular trigger responsible for induction of apoptosis is incompletely defined, but appears to be present in all mammalian cells at all times and is conserved across species. Not surprisingly, induction of apoptosis is tightly controlled. Several regulatory genes have been identified, including the Bcl-2 family, p53 and Fas [21, 25]. The molecular machinery responsible (the "executioner") includes a cysteine protease (CPP-32 in mammals) that may inactivate DNA repair enzymes [19, 23, 35]. The cellular changes characteristic of apoptosis include a "flip" of phosphatidylserine from the inside to the outside surface of the cell membrane [33], cytoplasmic shrinkage, little or no swelling of organelles (mitochondria), membrane budding and fragmentation that include mitochondria or nuclear fragments, and chromatin condensation consisting of DNA fragments. These membrane changes lead to rapid recognition and cell elimination by neighbouring phagocytes, which may make apoptotic cells difficult to locate using conventional microscopic techniques. The techniques that are used to detect apoptosis include light and electron microscopy (fig.

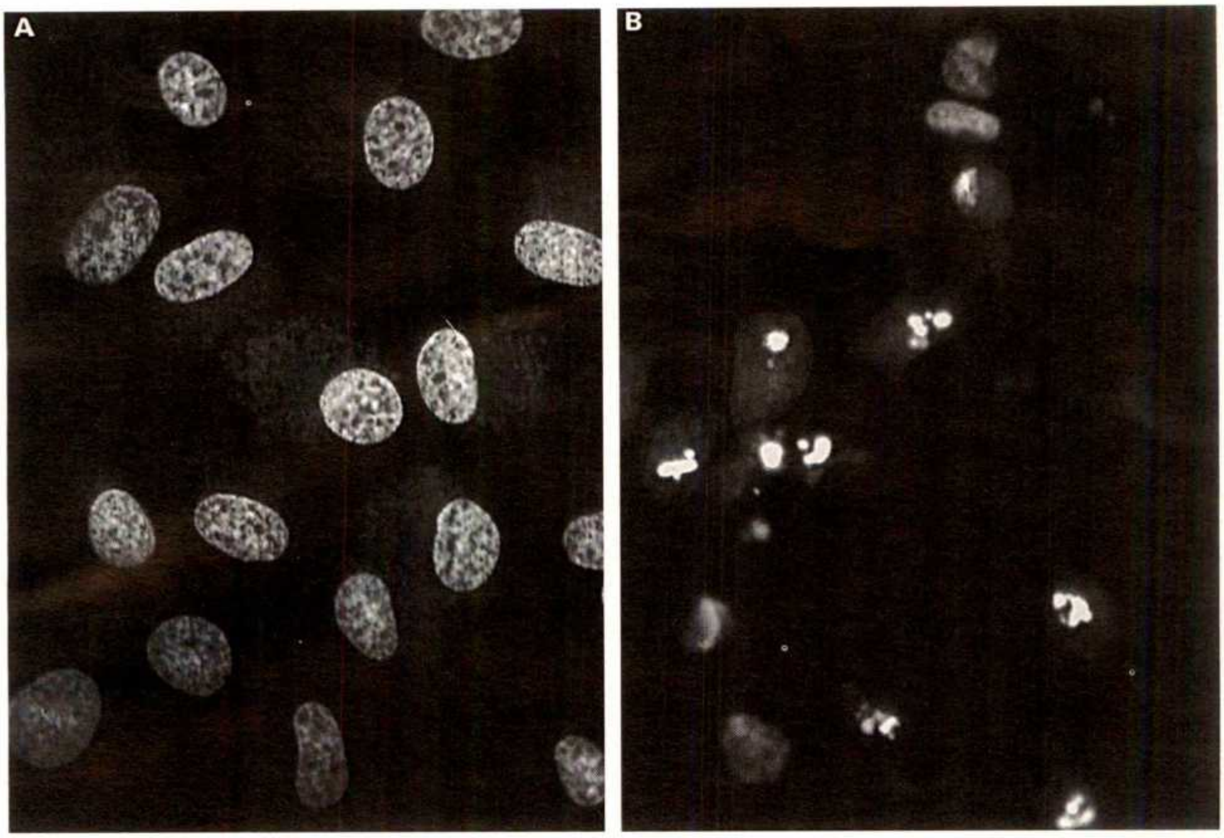

Figure 3 Normal cultured porcine aortic endothelial cells (A, × 360 magnification) stained with nuclear binding dye Hoechst 33342. The nuclei are smooth and ovoid. Nuclei from cells challenged with endotoxin followed by arsenite are compact and fragmented ("apoptotic bodies", B, × 360 magnification).

Table 2 Comparison of characteristics of oncosis and apoptosis

Oncosis—death by swelling	Apoptosis—death by shrinkage
(1) Swelling of organelles and cytoplasm	(1) Shrinkage of cytoplasm
(2) Small dense chromatin clumps which are not sharply defined	(2) Large, dense, often crescent-shaped aggregates of chromatin and nuclear fragmentation
(3) Swelling and eventual disintegration of organelles (e.g. mitochondria and endoplasmic reticulum)	(3) Organelles maintain structural integrity
(4) Early focal disruption of the plasma membrane with blebbing	(4) Plasma membrane maintains integrity early; later stage characterized by budding of membrane, frequently containing organelles
(5) DNA agarose gel electrophoresis demonstrates smear pattern indicative of randomized breakdown	(5) DNA agarose gel electrophoresis demonstrates "ladder" pattern of discrete internucleosomal breakdown
(6) Cells rupture and contents are released causing inflammatory response	(6) Cells are either ingested whole by phagocytic cells, or they break into membrane-bound fragments (apoptotic bodies) which then are ingested

1), end-labelling of DNA fragments (fig. 2), DNA agarose gel electrophoresis and binding of nuclear-specific dyes (fig. 3).

Despite the relatively clear distinction which can be made morphologically (oncosis *versus* apoptosis is compared in table 2), examination at the molecular level demonstrates considerable overlap. For example, both oncosis and apoptosis have been associated with increases in intracellular Ca^{2+}, which activate a number of enzymes including phospholipases, endonucleases, proteases and protein kinases. In addition, the adaptive response to ischaemic, inflammatory, oxidant and heat-induced stress involve changes in gene expression that are shared by both types of cell death. Further, the same type of injury can result in cell death by either mode. Indeed, Kerr's original description of apoptosis ("shrinkage necrosis") was based upon differentiation of shrunken necrotic cells from the more common swollen necrotic cells in ischaemic liver tissue [16].

Pathophysiology of organ dysfunction

Studies of cellular responses *in vivo* indicate that injury activates the programmes of stress gene expression reviewed above. For example, the hepatocellular response to ischaemic injury in a porcine model of MODS includes activation of the acute phase, oxidative, and heat shock responses [7]. In contrast, neighbouring hepatic endothelial cells in this model did *not* stain for heat shock gene expression (*in situ* hybridization), suggesting that there are cell-specific differences in the genetic response to similar injury. A subsequent investigation conducted *in vitro* under more controlled conditions explored the time-course and interaction of these cellular stress responses. Human hepatoblastoma (HepG2) cell lines were treated with inducers of the acute phase response (IL-1 and TNF) and heat shock responses separately and in combination. The results indicated that shock-induced expression of these responses were distinct, exclusive and prioritized [6]. Specifically, the heat shock stress response, the most primitive and highly conserved of stress gene responses, was capable of extinguishing expression of other genetic programmes [5, 28]. These data suggest that hepatocyte injury of sufficient severity to trigger the heat shock response can prevent production of system-stabilizing acute phase proteins and other adaptive responses. The liver's response to such a systemic injury, from the host's perspective, would appear to be inadequate and indicative of failure. Hepatic dysfunction in this model of MODS, thus, would result from execution of primitive, protective genetic responses that give individual cells priority over the organism.

The sequence of stress gene programme activation also appears to be important. In one *in vitro* model, the endothelial cell response to arsenite, an inducer of the heat shock response, and to endotoxin, an inducer of the acute phase response, were studied. The results indicated that induction of the heat shock response could protect against endotoxin-induced cytotoxicity, but reversing the order—endotoxin challenge followed by induction of the heat shock response—increased cell death by apoptosis [5]. The effect of the heat shock response was not the result of a detrimental effect of the heat shock proteins themselves, but rather to the heat shock-induced inhibition of further protein synthesis [5]. An important hypothesis drawn from these data is that two independent programmes of stress gene expression can interact, depending on the sequence, to either protect the cell or trigger cell death by suicide (apoptosis). This may explain the absence of endothelial cells expressing heat shock proteins after shock *in vivo* ([7], discussed above), as endothelial cell apoptosis may have resulted in their subsequent removal by phagocytes before *in situ* staining. Thus, endothelial cell dysfunction and death in this model result from the adverse interaction of two usually beneficial patterns of stress responses. The mechanism responsible may involve alterations in the cellular redox potential and changes in nuclear transcription factor activity [unpublished observations]. For example, in the cultured endothelial cell model, reducing agents such as *N*-acetyl-L-cysteine and dithiothreitol block induction of endotoxin/arsenite-induced endothelial cell apoptosis, implicating ROS in the induction of apoptotic cell death [1, 2]. This raises the possibility that the adaptive response produced by oxidative stress could modulate the interaction of the acute phase and heat shock responses, and may participate in determining the fate of the cell.

Apoptosis may also contribute to failure of organs in other settings, in particular, septic shock. Injection of Gram-negative or Gram-positive bacteria [34], endotoxin [34, 36], or caecal ligation and puncture [4] induced apoptosis in rodent thymocytes. Zhang and colleagues [36] reported that mice injected with lipopolysaccharides had apoptosis not only in the thymus, but also in the spleen, bone marrow and endothelial cells. Norimatsu and associates injected swine intravenously with 0.5 mg kg^{-1} *Escherichia coli* endotoxin and noted that cells in both thymus and mesenteric lymph nodes underwent apoptosis [24]. In a recent report, Rogers and colleagues demonstrated apoptosis in the liver of mice infected with *Listeria monocytogenes* [27]. Apoptosis has also been reported in rabbit heart [12] and rat kidney [29] after ischaemia/reperfusion injury. Collectively, these investigations suggest that apoptotic cell death may be a principal mechanism responsible for organ dysfunction and death as a consequence of shock-induced injury.

Conclusions—from basic science to therapy and prevention

Cell injury occurs as a result of physical, chemical or biological insults or from vital substrate deficiency. These insults induce expression of adaptive stress response gene programmes that include the ischaemic/hypoxic stress, oxidative stress, heat shock and acute phase responses. If the severity of the injury exceeds the ability of the cell to adapt, then cell death occurs. The processes of cell death include cell death by ischaemia, accident or suicide. Morphologically, ischaemic and accidental deaths are usually manifested by cytoplasmic swelling (*oncosis*) and suicidal cell death by cytoplasmic shrinkage (*apoptosis*). However, this terminology lacks precision, as some "accidental" causes of cell death, such as heat, can also induce apoptosis [18]. The molecular machinery responsible for cell death and the boundaries between apoptosis and other modes of cell death remain to be determined [14].

The sequence and interaction of the acute phase, heat shock and oxidative stress responses appear to be a determinant of the fate of the cell. The pattern of cell responses is injury- and tissue-dependent and may help to explain differences in the course and nature of organ failure. Specifically, it appears that stimuli sufficient to trigger the heat shock response can precipitate cell (and organ) failure by blocking initiation of other programmes of stress gene expression (e.g. the system stabilizing acute phase response of hepatocytes). In other cells (e.g. the endothelium), the sequence of acute phase followed by heat shock response may result directly in apoptotic cell death. The function of shock-induced apoptosis is not known, but it may contribute to control of immune cell proliferation in thymus, spleen, bone marrow, and lymph nodes and modulation of the inflammatory response.

MODS is the result of cellular responses to a stimulus of either enormous magnitude or distribution. The stimulus itself frequently does not result directly in cell death, but rather the magnitude of the appropriate response from stimulated cells collectively is injurious to the organism. For instance, small doses of i.v. lipopolysaccharide (endotoxin) in humans are not directly cytotoxic, but lead to the release of the intercellular mediators, such as cytokines, that amplify the stimulus and trigger organ dysfunction [30]. Unfortunately, attempts to attenuate the magnitude of this response by attacking the circulating mediators themselves (e.g. anti-endotoxin and anti-cytokine therapies) have failed to improve patient survival in randomized, prospective trials [22]. These negative data forced a broad re-examination of the treatment strategies for the systemic inflammatory response syndrome (SIRS) and MODS and a change in focus from extracellular signals (i.e. the mediators) to the intracellular responses to these signals [8]. Recent symposia have addressed this important issue (e.g. "The Future of Sepsis Research", August 1995, Bethesda, MD, USA, sponsored by the American College of Chest Physicians, National Institute of Allergy and Infectious Disease, National Heart, Lung, and Blood Institute and National Institutes of Health, USA).

A NEW THERAPEUTIC STRATEGY: MODULATION OF CELLULAR RESPONSES TO INJURY

In summary, the data presented above are consistent with a new hypothesis on the cellular origin of MODS, one that has emerged as a result of a change in focus from the extracellular to the intracellular response to injury. They suggest that there are distinct, exclusive, and prioritized genetic programmes expressed in response to cell injury that are specific to cell type and injury. The effects of these stress response gene programmes are usually cytoprotective, but when activated in sequence, they can precipitate apoptotic cell death. Recent success in modulating induction of apoptosis with reducing agents [1], anti-oxidants [2], inhibitors of protein synthesis [5], anti-TNF antibody [34] and steroid antagonists [3] suggests that pharmacological control in the clinical setting is possible. A complete understanding of the type, sequence, interaction and impact of stress gene responses to injury will form the basis for novel gene-directed therapy for the treatment and prevention of MODS.

The immuno-inflammatory cascade

H. F. Galley and N. R. Webster

Severe sepsis complicated by multi-organ dysfunction syndrome (MODS) is a major cause of death in intensive care units, with a mortality rate in excess of 50%. The outcome is determined not only by the infection but also by the intensity of the immuno-inflammatory response. This response is essential for the resolution of infection but may occur in an uncontrolled manner causing damage to the host. The pronounced synergy and interaction of the components of the immune system dictate that modulation may result in either immunostimulation or immunosuppression. Coordination of the host immune response to infection and inflammation in terms of expression of the effector molecules is vital to an optimum response (Fig. 1).

Innate and acquired immunity

Mediators of immunity and inflammation (families of protein and lipid molecules) are part of an intercellular signalling language which allows cells/tissues/organs to take in new information and, based on past experience, decide what to do next. There are essentially two components to the immune response—innate (non-specific) and acquired (antibody-mediated) immunity.

The body possesses a range of barriers to prevent micro-organisms from entering, including the skin, mucous secretion, ciliary action and gastric acid. If these barriers are crossed micro-organisms are destroyed by soluble factors such as lysozyme and by phagocytosis with intracellular digestion (termed innate immunity). The complement system is a multi-component triggered enzyme cascade which attracts phagocytes to micro-organisms increasing capillary permeability and neutrophil chemotaxis and adhesion. Specific acquired immunity in the form of antibodies inactivates micro-organisms which are not destroyed by the innate immune system. Such micro-organisms either fail to activate the complement pathway or prevent activation of phagocytes. The cells involved in innate immunity include "professional" phagocytes (polymorphonuclear neutrophils, mast cells and macrophages) and "non-professional" phagocytes (endothelial cells and hepatocytes). Cells infected with viruses and parasites are killed by large granular lymphocytes termed natural killer (NK) cells, and eosinophils.

Acquired immune defences against specific micro-organisms (antigens) form the second component of the immune response. Antibodies activate the complement system, stimulate phagocytic cells and specifically inactivate micro-organisms. Lymphocytes, the basis of the acquired immune defence system, consist of antibody-producing plasma cells derived from B-lymphocytes, and T-lymphocytes which control intracellular infections. Binding of micro-organisms to antibodies on the cell surface of B-cells leads to preferential selection of these antibody-producing cells. This is termed priming, and subsequent responses are faster and amplified, and provide the basis of vaccination. T-cells exploit two main strategies to combat intracellular infections—secretion of soluble mediators which activate other cells to enhance microbial defence mechanisms, and production of cytolytic T-cells which kill the target organism. Adaptive selection of specific T-cell subsets occurs in response to local balance of cytokine concentrations [12].

Cytokines

Orchestration of immune and inflammatory responses depends upon communication between cells by soluble molecules given the generic term cytokines, including chemokines, interleukins (IL), growth factors and interferons (IFN). They are low molecular weight secreted proteins which regulate both the amplitude and duration of the immune/inflammatory responses (table 1). They have a transient action which is tightly regulated. Cytokines are highly active at very low concentrations, combining with small numbers of high affinity cell surface receptors and producing changes in the patterns of RNA and protein synthesis. They have multiple effects on growth and differentiation in a variety of cell types with considerable overlap and redundancy between them, partially accounted for by the induction of synthesis of common proteins. Interaction may occur in a cascade system in which one cytokine induces another, through modulation of the receptor of another cytokine and through either synergism or antagonism of two cytokines

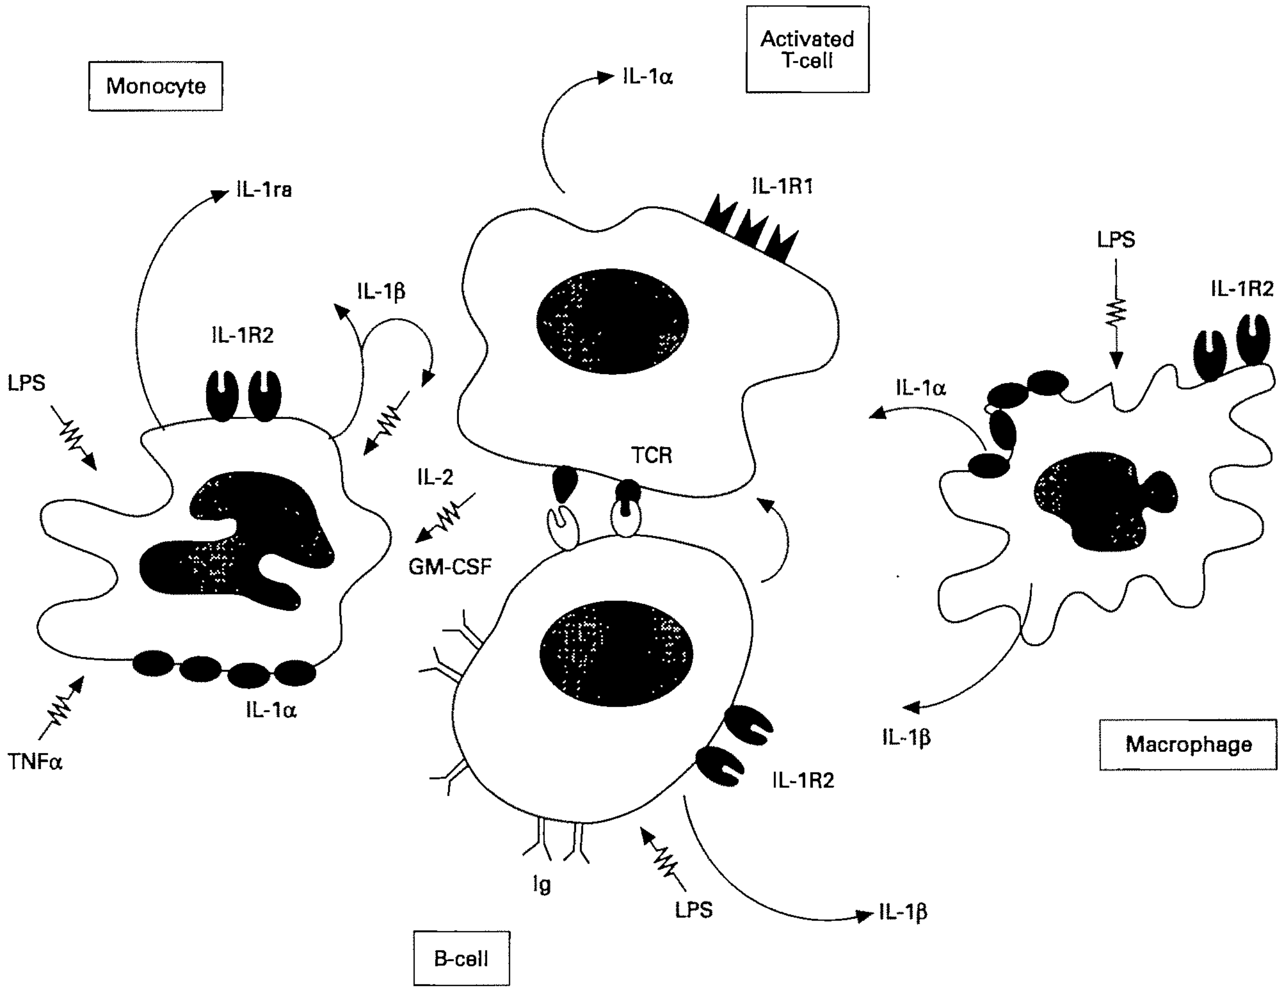

Figure 1 Schematic diagram showing the interaction between monocytes, macrophages, activated T-cells and B-cells during the immuno-inflammatory response. (GM-CSF, granulocyte-macrophage colony stimulating factor; Ig, immunoglobulin; IL-1α, interleukin 1α; IL-1β, interleukin 1β; IL-1ra, interleukin 1 receptor antagonist; IL-1R1, interleukin 1 receptor type I; IL-1R2, interleukin 1 receptor type II; IL-2, interleukin 2; LPS, lipopolysaccharide; TCR, T-cell receptor; TNFα, tumour necrosis factor α.)

acting on the same cell. Cytokines should not be considered as having identifying labels for being growth stimulators or inhibitors and pro- or anti-inflammatory actions. Their specific actions depend on the stimulus, the cell type and the presence of other mediators and receptors.

Chemokines are a family of small, pro-inflammatory molecules characterized by four conserved cysteine residues. The α-chemokines have two pairs of cysteine residues separated by a variable amino acid and chemoattract neutrophils (e.g. interleukin 8, platelet basic protein, epithelial neutrophil activating peptide) whereas β-chemokines have two adjacent pairs of cysteine groups and are chemotactic for monocytes/macrophages (e.g. platelet factor 4, monocyte chemotactic protein 1, macrophage inflammatory protein 1) and T-cells (e.g. RANTES). Chemokines have been described as having more restricted actions than cytokines, but this is more likely to be the result of differential expression of receptors [9]. Interferons (IFN α, β, γ) are a family of broad spectrum antiviral agents which also modulate the activity of other cells, particularly IL-8 and platelet activating factor (PAF) production, antibody production by B-cells and activation of cytotoxic macrophages [5]. Growth factors regulate the differentiation, proliferation, activity and function of specific cell types [17]. The best known are colony stimulating factors which cause colony formation by haematogenic progenitor cells (e.g. granulocyte-macrophage colony stimulating factor or GM-CSF). Other examples include factors which regulate the growth of nerve cells, fibroblasts, epidermis and hepatocytes.

In addition to the low molecular weight protein mediators, there are also lipid mediators of inflammation which include PAF and arachidonic acid metabolites. Platelet activating factor is a labile alkyl phospholipid released from a variety of cells in the presence of antigen and leucocytes in response to immune complexes. In addition to its platelet effects, the actions of PAF include the priming of macrophages to other inflammatory mediators and alterations of microvascular permeability [11]. Arachidonic acid metabolites include the prostaglandins, leukotrienes, HETE and HPETE, all of which have profound inflammatory and vascular actions, and may regulate and be regulated by, other cytokines.

Tumour necrosis factors (TNF) α and β have a vast range of similar effects and are usually referred to as inflammatory cytokines [2]. They have a central role in initiating the cascade of other cytokines and factors that make up the immune response to infection. The wide variety of effects is attributable to the ubiquity of their receptors, their ability to activate multiple signal transduction pathways and their ability to induce or suppress an array of genes including those for growth factors, cytokines, transcription factors, receptors and acute phase proteins. Although both TNFs have similar biological activities, regulation of the expression and processing of the two is quite different.

Control of adaptive T-cell selection

The major histocompatibility complex (MHC) includes genes encoding class I and II cell surface glycoproteins whose function is to present antigenic peptides to T-cells. Regulation of MHC gene expression, e.g. by cytokines (table 1), plays a fundamental role in the immune system, since alterations of cell surface expression of class I or II molecules can affect the efficiency of antigen presentation. T-lymphocytes consist of two subsets: T helper (Th)-cells which recognize class II MHC molecules and which produce IFNγ and other macrophage-activating factors; cytotoxic or killer T-cells which recognize both specific antigens and class I MHC molecules on the surface of infected cells.

Circulating Th-cells are capable of unrestricted cytokine expression and are prompted into a more restricted and focused pattern of cytokine production depending on signals received at the outset of infection [12]. Th-cells can be classified according to the pattern of cytokines they produce. Th1 category cells secrete a characteristic set of cytokines which push the system towards cellular immunity (cellular cytotoxicity). Th2-cells are associated with humoral or antibody-mediated immunity. Typically Th1-cells secrete IL-2, IFNγ, TNFβ and transforming growth factor β (TGFβ) whereas the Th2-cells secrete IL-4, IL-5, IL-6, IL-9, IL-10 and IL-13 and also help B-cell antibody production. Both cell types produce IL-3, TNFα and GM-CSF. Interleukins 12 and 4 have been identified as early inducers of Th1 and Th2 responses respectively, and therefore the local balance of these cytokines is an important determinant of subsequent immune responses. Understanding the influence of antigen-independent cytokine production on the subsequent acquisition of adequate immune responses to an infection is clearly important.

Receptors and antagonists

The biological activities of cytokines are regulated by specific cellular receptors. Often these receptors comprise multiple subunits providing phased stages of activation and biological action. For example, the IL-2 receptor complex consists of three subunits, IL-2Rα, IL-2Rβ and IL-2γ. Although the IL-2Rα/β combination can bind IL-2, IL-2Rγ is also required for high affinity binding, ligand internalization and signalling which are required for maximal effect [14]. Other cellular receptors exist in more than one type which act alone but have different binding affinities for different forms of a cytokine protein (e.g. IL-1 receptor type I binds IL-α better than IL-1β, and IL-1 receptor type II has more affinity for IL-β). Binding of a cytokine to one type of receptor may result in interactions with another receptor; the two receptors for TNF, for example, use ligand passing in which TNF binds transiently to receptor type I, with full signal transduction, but may then move onto the type II receptor with activation of another signal for apoptosis or programmed cell killing [20].

Soluble cytokine receptors have been identified which compete with membrane-bound receptors, thus regulating cytokine signals. Exceptions to this are soluble receptors for IL-6 and ciliary neurotrophic factor which act as agonists rather than antagonists [19]. Such soluble receptors may be membrane-bound receptors which are shed into the circulation either intact or as truncated forms (e.g. soluble TNF receptors, sTNF-R), or may begin as related precursor molecules which are enzymatically cleaved (e.g. IL-1R). Soluble receptors may appear in response to stimuli as part of a naturally occurring independent regulatory process to limit the deleterious effects of a mediator (e.g. sTNF-R), but some soluble receptors have little binding activity and may represent superficial and unimportant losses of cellular receptors (e.g. the soluble form of the IL-2Rα). Soluble cytokine receptors not only mediate biological activity but control desensitization to ligands by reduced availability, decreased signalling and by stimulating cellular mechanisms which can result in lack of activity.

The biological actions of some cytokines are also regulated by receptor antagonists. The receptor antagonist for IL-1 (IL-1ra) competes with cell receptors for IL-1, but when bound does not induce signalling. IL-1ra binds to cell receptors much more avidly than to soluble receptors, such that soluble receptors will have little effect of the inhibitory action of the receptor antagonist. The soluble receptor also inhibits activation of the pro-IL-1β precursor. The appearance of IL-1ra is independently regulated by other cytokines as part of the inflammatory process [4].

Mechanisms of multi-organ failure

Severe infection leads to the appearance of endotoxin or lipopolysaccharide (LPS) in the bloodstream which triggers the innate immune responses such as activation of phagocytic cells and activation of the alternative complement cascade, leading to the production of the primary pro-inflammatory mediators, TNF and IL-1. Secondary mediators including other cytokines, prostaglandins and PAF are then released, with further activation of complement and the acute phase response, expression of adhesion molecules, T-cell selection, antibody production and release of oxygen-derived radicals [3, 7, 21]. Other toxins and cellular debris must also trigger such a systemic inflammatory response, since this process occurs in the absence of LPS release.

Local effects of the inflammatory response are essential for the control of infection. Prolonged systemic exposure to high concentrations of cyto-

Table 1 Sources and biological effects of the immune mediators (ARDS, acute respiratory distress syndrome; GM-CSF, granulocyte-macrophage colony stimulating factor; G-CSF, granulocyte-colony stimulating factor; IFN, interferon; IgA, immunoglobulin A; IgG, immunoglobulin G; IL, interleukin; IL-1ra, interleukin 1 receptor antagonist; MHC, major histocompatibility complex; mRNA, messenger RNA; NK, natural killer cells; NO, nitric oxide; NOS, nitric oxide synthase; ODFR, oxygen-derived free radicals; PAF, platelet activating factor; Pg, prostaglandin; TGF, transforming growth factor; TNF, tumour necrosis factor.)

Mediator	*Source*	Biology activity	*Effects on other cells*
IFNα IFNβ	T-cells B-cells Macrophages Fibroblasts	Pyrogenic; cytotoxic.	Macrophages (increases class I MHC antigens, IL-1, PAF production); B-cells (proliferation, differentiation); T-cells (proliferation); chemotactic.
IFNγ	T-cells NK cells	Pyrogenic; antiviral; cytotoxic; anti-tumour effect; mimics septic shock; causes release of NO and ODFRs; and upregulates IL-1 and PAF production	Macrophages (increases class I MHC antigens, IL-1, PAF production, downregulates IL-2 mediated IL-8 mRNA); B-cells (proliferation and differentiation); chemotactic for monocytes; stimulates formation of adhesion molecules.
TNFα	Neutrophils Lymphocytes NK cells Endothelial cells Smooth muscle cells	Pyrogenic; cytotoxic; anti-tumour effect; mimics septic shock; promotes angiogenesis; causes release of NO and ODFRs; induces or suppresses gene expression for cytokines, receptors and acute phase proteins.	Wide variety of effects due to ability to mediate expression of genes. Important role in host resistance to infection as immuno-stimulant and mediator of the inflammatory response. Promotes haematopoiesis. Important role in intercellular communication.
IL-1	Macrophages Endothelial cells Fibroblasts Hepatocytes	Pyrogenic; cytotoxic; anti-tumour effect; promotes angiogenesis; causes release of NO and ODFRs; induces prostaglandin synthesis; initiates the acute phase response.	Macrophages (TNF and IL-6 production); B-cells (proliferation, differentiation; T-cells (proliferation) chemotaxis; formation of adhesion molecules; haematopoiesis.
IL-2	T-cells	Pyrogenic; anti-tumour effect; mimics septic shock; causes release of ODFRs.	B-cells and T-cells (proliferation, differentiation, release of IgG from activated B-cells); chemotaxis; augments neutrophil and macrophage function; formation of adhesion molecules.
IL-4	T-cells B-cells Macrophages	Cytotoxic; anti-tumour effect; inhibits induction of nitric oxide synthase; inhibits release of superoxide by macrophages; numerous anti-inflammatory effects.	Macrophages (suppresses activation, upregulates class II MHC antigens, inhibits IgG receptor expression, inhibits expression of IL-1, IL-6, IL-8, TNF, stimulates IL-1ra expression); B-cells and T-cells (proliferation, differentiation, enhances antigen-presenting capacity); chemotaxis; formation of endothelial cell adhesion molecules; haematopoiesis.
IL-6	T-cells Macrophages Endothelial cells Fibroblasts Hepatocytes	Cytotoxic; anti-tumour effect; mimics septic shock; causes release of ODFRs; induces hepatic acute phase proteins	B-cells (differentiation, antibody production); T-cells (activation, proliferation, differentiation, induces IL-2 production); formation of adhesion molecules; haematopoiesis.

kines and other components of the immuno-inflammatory cascade may contribute to the development of MODS. Damage and activation of the endothelium, which plays a pivotal role in the regulation of haemostasis, vascular tone and fibrinolysis, have profound consequences. The endothelium produces several substances which regulate inflammation and regional perfusion, including nitric oxide, vasoactive arachidonic acid metabolites and cytokines [18]. Changes in the balance of concentrations of these substances may contribute to the pathogenesis of the inflammatory response during sepsis and injury. Phagocytic cells are in constant contact with the endothelium and disturbance of the relationship between these two cell types may result in direct tissue damage as a result of local production of oxygen-derived free radicals, hypochlorous acid and proteolytic enzymes. Another hypothesis to explain the observed tissue damage and organ dysfunction is that of local tissue ischaemia and hypoxia as a result of microthrombi formed by a coagulopathy or platelet or white cell aggregates. There is evidence for all of these mechanisms and it is probable that the pathogenesis of MODS and organ failure is diverse and complex and is unlikely to be attributable to a single mechanism.

Potential for therapy

Both soluble receptors and monoclonal antibodies directed against receptors can be used to block the interaction of a cytokine with its receptor. This then prevents transduction of the appropriate biological signal in the target cell. The cloning of genes encoding cytokine receptor chains and the characterization of their soluble forms has resulted in new approaches to anti-cytokine therapy. Injection of a recombinant soluble receptor might prevent the deleterious effect of excessive cytokine production. In addition to soluble receptors, monoclonal antibodies which block cellular cytokine receptors can be used as anti-cytokine therapy. However, these small

Table 1—(cont.)

Mediator	*Source*	Biology activity	*Effects on other cells*
IL-8	T-cells Macrophages Endothelial cells Hepatocytes Neutrophils Fibroblasts	Angiogenic; leucocyte infiltration in septic shock and ARDS.	Neutrophils (activation); upregulates cell adhesion molecules; chemotactic for PMNs.
IL-10	T-cells B-cells Macrophages	Inhibits induction of nitric oxide synthase; suppresses synthesis of ODFRs; may be immunostimulatory or immunosuppressive.	Macrophages antigen presenting capacity, downregulates class II MHC antigen expression, suppresses PgE2, TNF, IL-1, IL-6, IL-8 production); B-cells (induces IgA synthesis, enhances survival, upregulates IL-2 receptors); T-cells (inhibits IFNγ); neutrophils (inhibits pro-inflammatory cytokine synthesis, upregulates IL-1ra expression).
G-CSF	Macrophages Endothelial cells	Proliferation, differentiation and activation of neutrophils; mimics septic shock; causes release of ODFRs.	Neutrophils (proliferation, prolongs survival, enhances antibody dependent cytotoxicity and superoxide anion production); chemotactic for granulocytes and monocytes.
GM-CSF	T-cells B-cells Macrophages Endothelial cells Fibroblasts	Proliferation, maturation and function of haematopoietic cells; causes release of ODFRs.	Neutrophils (proliferation, differentiation, prolongs survival, increases superoxide, leukotriene, PAF, arachidonic acid release, enhances phagocytic activity, inhibits IL-8 production and neutrophil migration); monocytes (proliferation, differentiation, induces IL-1, IL-8 and TNF release); chemotaxis; formation of adhesion molecules; angiogenesis; haematopoiesis.
TGFβ	Platelets Fibroblasts Monocytes	Stimulatory or inhibitory effects on proliferation and differentiation of many cell types depending on type of cell, growth conditions, cell differentiation state, and presence of other growth factors; modulates cellular and humoral immune responses; suppresses chemokine-mediated NO release.	Lymphocytes (suppresses B and T-cell proliferation, inhibits NK activity, inhibits IgG and IgM secretion, upregulates B-cell IgA secretion); macrophages (induces secretion of growth factors); chemotactic for macrophages.
IL-1ra	Macrophages Endothelial cells Neutrophils Fibroblasts	Blocks the biological activity of IL-1 by competing for the IL-1 by competing for the IL-1 receptor.	
PAF	Macrophages Endothelial cells Neutrophils	Activates and aggregates platelets; mimics endothelial alterations of septic shock; induces release of ODFRs.	Macrophages (enhances IL-1, IL-2 and TNF production); intracellular messenger in neutrophils; causes release of lysosomal enzymes; chemotactic for neutrophils; formation of adhesion molecules.

molecules have short half-lives and therefore derivatized molecules with longer half-lives and higher affinity have now been developed. However, it has been shown that cytokine complexed to such binding proteins is still available for receptor binding [10]. It is possible that these complexes can still act as agonists *in vivo* depending on concentrations of other mediators and relative receptor expression. Another approach to minimizing the deleterious effects of the uncontrolled inflammatory process is to blunt the final common pathways of damage (i.e. using either agents which decrease free radical production or antioxidants which inactivate free radicals as they are produced).

Monoclonal antibodies to TNFα have been used both in clinical and animal studies [22]. The use of sTNF receptors has also been evaluated in sepsis [1, 23]. The naturally occurring IL-1 receptor antagonist has been studied in two large clinical trials [15]. It is also possible to modulate the production of TNF at the mRNA level using pentoxyphylline, and there have been several promising animal studies [8]. Specific chemical antagonists, for example against PAF, have also been evaluated in patients with sepsis.

Blockade of any single or combined inflammatory mediator may not be successful for a number of reasons. First, the immuno-inflammatory process is a normal response to infection and is essential not only for the resolution of infection but also for the initiation of other adaptive stress responses required for host survival (e.g. acute phase and heat shock responses) [16]. Second, the profound redundancy of action of many cytokines means that there are many overlapping pathways for cellular activation and further mediator release. In addition, the synergism of actions and effects of many cytokines suggests that imbalance in the process of the immune response may be adversely affected by inhibition of a single agent. We also suggest that exogenously administered anti-cytokine therapy may have hitherto unrecognized effects caused by interaction with naturally occurring immunomodulators or their receptors [10]. Finally, the timing of any potential anti-cytokine therapy is clearly crucial [24]. Strategies designed to predict the activation of specific components of the inflammatory response may thus be useful. It is also possible that specific cellular targeting of such therapy may be more beneficial than global inhibition. Preliminary animal studies suggest that the therapeutic use of anti-inflammatory cytokines such as IL-10 and IL-13 may be beneficial in sepsis although as yet there have been no confirmatory clinical studies [6, 13].

Disturbance of leucocyte circulation and adhesion to the endothelium as factors in circulatory pathology

D. H. ADAMS AND G. B. NASH

Advances in molecular biology have given us the tools to dissect the mechanisms which control the circulation of leucocytes. In particular, a sequence of intermolecular adhesive interactions has been described which underlies leucocyte attachment to the vessel wall, and the factors which promote and limit these interactions have begun to be appreciated. These discoveries have led to a rekindling of interest in the inflammatory response arising from extravasation of neutrophils and to a growing understanding of the basis of lymphocyte recirculation and targeting to specific organs [9, 72, 97]. Much work has been based, of necessity, on *in vitro* model systems, but animal studies and intravital techniques have enabled the molecular concepts to be tested, so that there is growing confidence that they are indeed the basis of physiological and pathological processes. Multiple organ failure (MOF) is attended by disturbance of tissue perfusion and degradative damage associated with an extreme inflammatory response, which may arise, in part at least, from a loss of the normal mechanisms controlling leucocyte circulation and migration into tissue [109]. It is thus our aim to review the circulatory and adhesive behaviour of leucocytes (especially neutrophilic granulocytes or neutrophils), along with its molecular basis and control mechanisms, and to evaluate the evidence that disruption of the normal physiological processes contributes to pathologies such as MOF.

Circulation of leucocytes

LIFESPAN, CIRCULATION AND RHEOLOGY

Although a large proportion of mature leucocytes are circulating at any given time, their physiological function is not carried out in the vascular compartment. Thus, neutrophils circulate for about 7–10 h on average before migrating into tissue as part of an inflammatory response where they phagocytose and destroy foreign bodies and necrotic tissue. The neutrophils found in the systemic blood represent only about 50 % of the circulating pool, so that there is a marginated population travelling slowly through the lungs and microcirculation which can be mobilized rapidly, for example by exercise or catecholamines [12]. Monocytes circulate for a similar period, but then become resident in tissues as macrophages for a period up to months, acting as a potent source of mediators such as cytokines, and forming an active part of the phagocytic reticuloendothelial system in the spleen, liver and bone marrow. Lymphocytes have a more complex pattern of behaviour, because they are the only leucocytes that return to the blood via the lymphatic system after migration into tissue (i.e. recirculation; see Ager [19] for review). The tissue to which they migrate depends on their subtype and activation status (see below).

The transformation from a circulating leucocyte to a non-circulating or migrated leucocyte depends on changes in the cellular rheological properties of resistance to mechanical deformation and adhesiveness. Successful passage through the microcirculation is dependent on the deformability of the leucocytes (because capillary diameter is often less than the cell dimensions) and on maintenance of a non-adhesive response to the endothelium. As is made evident below, the endothelial cells lining the microvessels, particularly on the venous side, are not passive partners in the potential adhesive interaction. At this stage it is sufficient to realize that it is disturbance in the balance of physical forces which determines whether or not a cell becomes immobilized in the microcirculation (i.e. circulatory driving force *vs* resistance to deformation or *vs* adhesive interaction). In the "physiological" response, controlled adhesive interactions enable leucocytes to attach to the vessel wall, and modulation of cellular mechanical properties allows locomotion and migration into tissue. However, uncontrolled changes in adhesive or cellular mechanical properties or in circulatory forces may lead to trapping in microvessels that could be "pathological".

MECHANICAL FAILURE TO CIRCULATE—A CONTRIBUTOR TO CIRCULATORY DISORDER?

Outside of severely hyperleucotic leukaemias, it is generally considered that leucocytes do not contribute to the bulk flow resistance of the blood in large vessels. However, although outnumbered by red cells by about 700:1, leucocytes can contribute to the resistance to flow and distribution of flow in

(Br. J. Anaesth. 1996; **77**: 17–31)

Key words
Blood, leucocytes. Blood, flow.

microvessels [38]. This is because the intrinsic resistance to flow into a small capillary is about 1000-fold greater for a leucocyte than a red cell [28]. Thus, it has been recognized from intravital observations, including those made in humans, that even normal leucocytes travel very slowly into capillaries, have the ability to hold up "trains" of red cells and can cause stop–go flow in individual capillaries [13, 14]. This seems to apply to each class of leucocyte, although all evidently negotiate the microcirculation successfully in the steady state. Problems may arise, however, if perfusion pressure is reduced or if neutrophils, in particular, become activated.

Studies in animal models show that reduction of perfusion pressure, induced artificially or after shock, leads to plugging of capillaries by leucocytes and increase in flow resistance [13]. Moreover, the return of driving pressure to normal does not seem to enable perfusion to be completely recovered. A similar series of events follows arterial ligation, for instance in animal models of myocardial infarction [33]. It appears that initial trapping of "normal" leucocytes may be mechanical, but that a process of activation ensues for neutrophils, probably prompted by mediators released in the affected tissue (e.g. activated complement, eicosanoids or endothelial-derived factors such as interleukin 8 (IL-8) or platelet-activating factor (PAF)). Activation causes rapid rigidification of neutrophils because of the formation of actin polymer in the cytoplasm [34] and also increases their adhesive potential (see below). Actin polymerization is the motor for migration of leucocytes into tissue, but if stimulated at an inappropriate time it will inhibit their circulation. Adhesion, as well as enabling extravascular migration, may also promote vascular occlusion. Such activation-induced changes in mechanical and adhesive properties will tend to stop cells from being dislodged after return of perfusion pressure. Not only this, but reperfusion brings new leucocytes to the tissue, which are in turn activated by mediators and change their mechanical and adhesive properties [85]. Thus there is the potential for a vicious cycle of increasing vascular blockage followed by tissue damage arising from the lytic enzymes and oxidants known to be released by activated neutrophils (fig. 1) [64, 106].

That such a process follows ischaemic and inflammatory events has been demonstrated in animal models [13, 85, 107] and is evidenced in humans by findings of systemic activation of neutrophils and changes in their mechanical properties [62, 64, 65]. Thus, it may be that circulatory obstruction occurs locally in an "insulted" tissue but also becomes disseminated because of release of activated cells (e.g. those which do not respond rapidly enough to be trapped locally), stimulatory mediators, or both. Such mediators may act on circulating neutrophils and also on remote endothelial cells to change their adhesive properties (see below). The lung may act as a filter of activated cells because of its low perfusion pressure and peculiar microvascular structure, where cells must pass through a series of capillary segments without shunting. The basis of trapping might be mechanical, adhesive, or both, although animal studies suggest that mechanical changes alone can be sufficient [112]. Other organs, such as the spleen, liver and kidney may also be susceptible because of structural features which promote trapping of rigid cells. The mechanical factors likely to influence the sites of microvascular entrapment of leucocytes are summarized in figure 2.

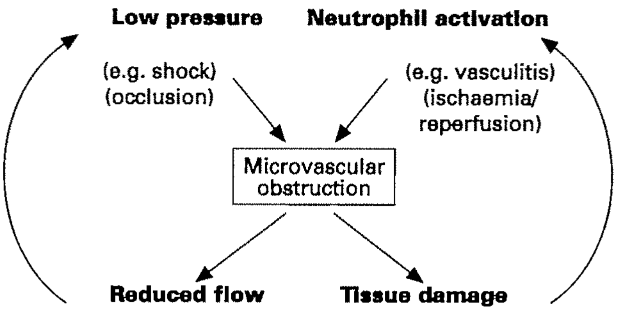

Figure 1 Mechanisms of obstruction of microvessels by neutrophils and the potential for feedback and establishment of a vicious cycle. If driving pressure is insufficient, neutrophils may become mechanically lodged in capillaries, leading to a further reduction in flow. Activation of neutrophils may cause trapping even at normal perfusion pressure, and the localized cells may induce vascular damage and release of mediators causing a second wave of activation.

CONSTRAINTS PLACED ON ADHESION BY CIRCULATION

Another important implication of circulatory dynamics and forces is that they impose constraints on the adhesive processes underlying leucocyte–endothelial interaction [45]. Leucocytes appear to adhere mainly in post-capillary venules where their velocities are relatively low but still of the order of hundreds of μm s^{-1}. Given the dimensions of the interacting cells and of the adhesion molecules on their surface, it is clear that individual molecular interactions have to be rapid to make the chance of capturing a cell finite. It has thus been realized that it is the kinetics of intermolecular adhesive interactions that are important (i.e. the "on-rates" relative to the flow rate, rather than the equilibrium affinity constants) in limiting cell capture [108]. Once adhesive bonds have formed, then they are put under stress by the fluid drag acting on the now stationary cell. These forces tend to break the bonds, and so capture might be followed by detachment, unless stabilizing bonds are formed rapidly. Alternatively, cells may roll slowly along the surface after capture because they are able to form new bonds at the front while bonds "peel" at the rear of the cell [104]. In addition, migration after stabilization implies that cells can unstick and re-stick themselves as they move, with flow forces acting on them continually until they have exited the vessel lumen. It would seem unlikely *a priori* that a single type of receptor–ligand interaction could have the necessary physical characteristics to support all stages of such a process in a controlled manner. Indeed molecular specialization appears to have been evolved in order to overcome this problem, and is described in the next section, along with our current understanding of how leucocyte adhesion to endothelium is achieved.

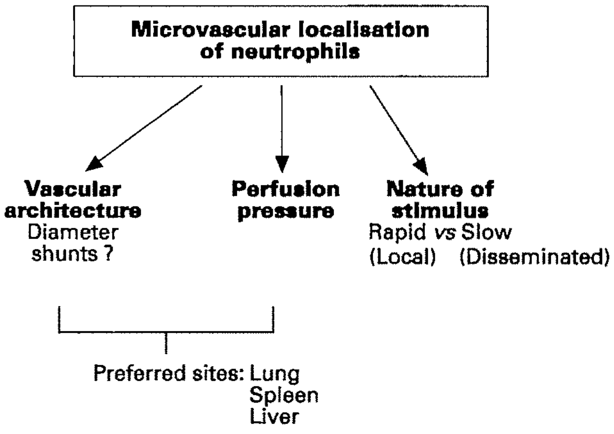

Figure 2 Factors influencing the site of mechanical trapping of neutrophils in tissue. Cellular resistance to flow is greatly dependent on vessel diameter [25], so that organs with narrow capillaries or sinusoidal structure, and with vascular architecture lacking shunts will be likely to filter cells, especially if the perfusion pressure is low (e.g. in the lungs). The same factors apply for rigidified neutrophils after activation, but if the mechanical response after activation is rapid, cells may be trapped in the tissue where the stimulus originated, while a slow response will lead to dissemination of the cells in the circulation.

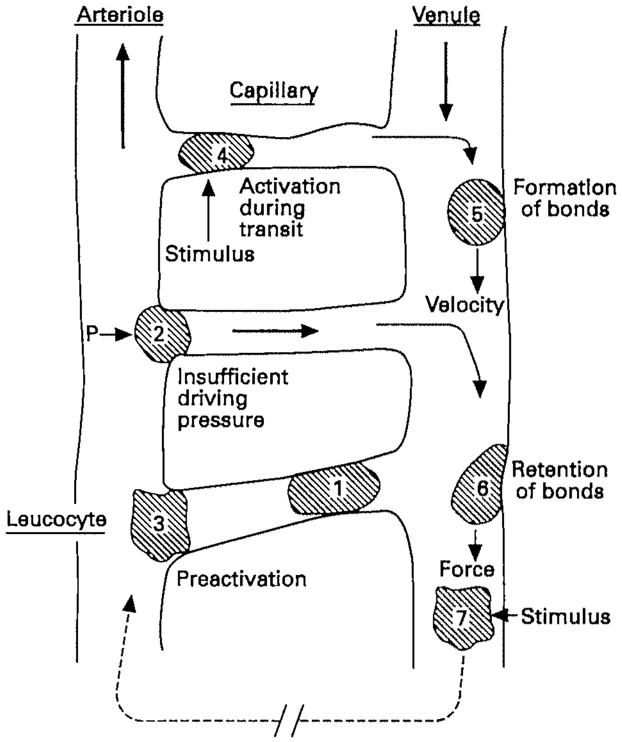

Figure 3 Mechanical factors affecting circulation of leucocytes passing from arterioles to capillaries to venules. Cells may need to undergo marked deformation and elongation to pass through capillaries (1), and may be unsuccessful if the perfusion pressure is reduced (2) or if they are activated by systemic (3) or local stimuli (4). Cells may adhere to venules if they can form bonds rapidly enough compared with flow rate (5) and if adhesive bonds can withstand shear forces (6). Cells failing to attach when stimulated (7) and released into the blood may be systemically active.

Figure 3 summarizes the role of physical forces in the microcirculation: leucocytes continue to circulate given adequate perfusion pressure, but if this driving force is reduced or if cells are activated by local or systemic inflammatory mediators, then inability to pass through capillaries may induce immobilization. Immobilization also arises from adhesive interaction with the vessel wall, dependent on the velocity of motion before capture and on the shear forces acting against subsequent stable attachment.

Leucocyte migration and recirculation

Leucocytes migrate extensively throughout the body to maintain immune surveillance and to mount rapid inflammatory responses to invading pathogens [6]. Different leucocytes have particular patterns of migration that are suited to their functional capacities. For instance, as mentioned above, neutrophils are a population of relatively simple effector cells that form an early response to infection or injury. They are rapidly recruited in large numbers to sites of inflammation where they are activated to release their intracellular contents. This activation is provided by general mechanisms and is not dependent upon the precise structure of the offending antigen, i.e. it is antigen-independent. Neutrophils do not recirculate and once they have entered tissue they either die by activation and release of cytoplasmic contents or they are removed by phagocytic macrophages.

T-lymphocytes, on the other hand, are a highly sophisticated population of cells, that are activated by specific antigens to which they have been programmed to respond. In most circumstances T-lymphocytes are recruited later and more selectively than neutrophils to diverse sites of inflammation. In contradistinction to neutrophils, T-cells have the ability to return to the circulation via the lymphatics. This permits them to recirculate through normal tissue and provide ongoing immune surveillance [72]. Their ability to respond to specific foreign peptides allows them to mount a highly selective response to invading foreign antigens [20, 99]. Naive T-cells (those that have not been exposed to antigen) recirculate almost entirely through lymphoid tissue where they are most likely to encounter their specific antigen in the specialized environment of the lymph node where optimal antigen presentation and activation can occur. However, after exposure to antigen in lymphoid tissue the naive T-cell returns to the resting state as a memory cell, primed to respond rapidly to a second encounter with antigen. In order to enhance its chances of re-encountering its specific antigen the memory T-cell recirculates preferentially through the tissue in which it was originally exposed to antigen [6, 72].

These subtle patterns of recirculation can be overcome in inflammation where release of pro-inflammatory factors results in the recruitment of a wider range of cell types. The composition of an inflammatory infiltrate will depend upon the nature of the pathogenic stimulus; for instance, the infiltrate of an allergic reaction may contain large numbers of eosinophils whereas T-cells and macrophages predominate in graft rejection and neutrophils at sites of acute bacterial sepsis. Furthermore, the inflammatory infiltrate changes over time, for instance an initial type I hypersensitivity reaction will provoke an influx of mast cells and eosinophils which will be

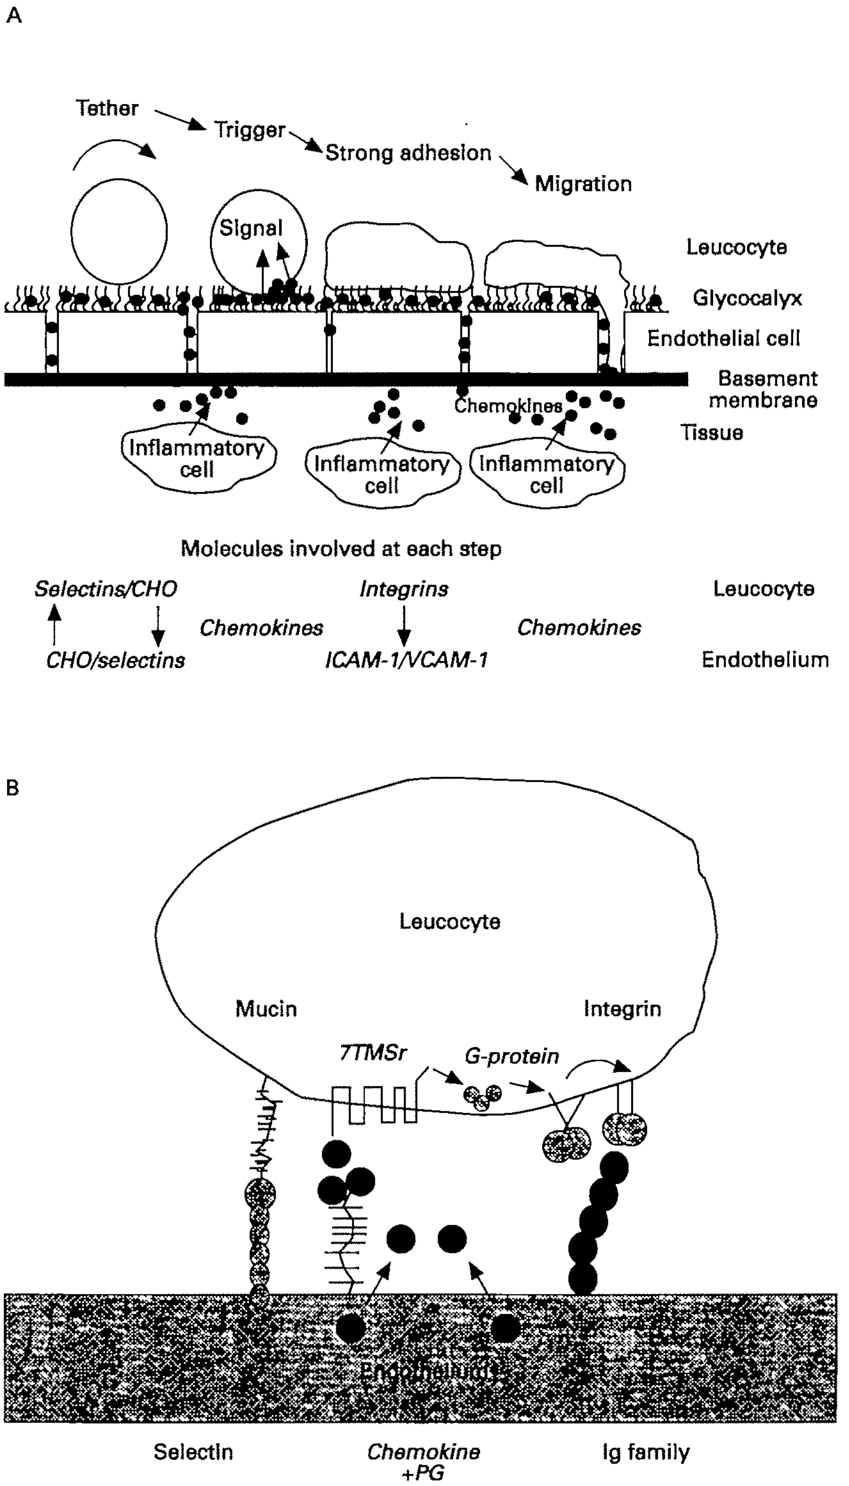

Figure 4 Adhesion to endothelium and subsequent transendothelial migration is regulated by a cascade of interactions between the leucocyte and the endothelium. A: The first step (primary adhesion) involves tethering of the leucocyte to the endothelium by comparatively weak and transient bonds provided by selectins on either the endothelium (e.g. E-selectin) or the leucocyte (L-selectin) that bind to carbohydrate receptors on the opposing cell. This allows the leucocyte to come into contact with pro-adhesive factors (typically chemokines) that are immobilized in the endothelial glycocalyx and provide a trigger for integrin activation and strong secondary adhesion. This strong adhesion is mediated by leucocyte integrins binding to members of the immunoglobulin superfamily on the vessel wall. The final step in the cascade is transendothelial migration which is promoted by chemotactic factors such as chemokines. Chemokines are produced by the endothelium itself or by inflammatory cells in the subendothelial tissues. B: Diagrammatic representation of the major molecules involved in the adhesion cascade between leucocytes and endothelium. The tethering step is provided by selectins and allows chemokines immobilized on proteoglycan in the endothelial glycocalyx to engage specific receptors on the leucocyte. This results in conformational activation of leucocyte integrins permitting their adhesion to endothelial receptors of the immunoglobulin family. In addition, chemokines promote cytoskeletal changes and the induction of motility.

followed later by macrophages and T-cells if the lesion becomes chronic. Such complex inflammatory responses must be mediated by specific mechanisms capable of recruiting particular subsets of leucocytes dependent on the inflammatory stimulus [97].

LEUCOCYTE RECRUITMENT TO TISSUE IS REGULATED BY SEQUENTIAL ADHESIVE INTERACTIONS WITH ENDOTHELIUM

Clearly leucocyte migration must be carefully regulated both to maintain immune surveillance and to enable different inflammatory responses to invading stimuli to be established. For instance, inappropriate recruitment of granulocytes to normal tissue could result in tissue damage from release of proteolytic enzymes and reactive oxygen intermediates whereas a failure of T-cells to migrate through normal tissue would impair immune surveillance. The fact that leucocytes must first recognize and then bind to the endothelium before they can migrate into tissue provides a powerful mechanism for regulating their recruitment. This adhesive interaction with endothelium is a dynamic process involving the activation both of the endothelium and the leucocyte [6, 97]. Leucocyte recruitment occurs when a cascade of sequential interactions between the leucocyte and the endothelium results in the flowing leucocyte coming into contact with the endothelium, stopping at the vessel surface and then migrating into tissue in a regulated manner.

The first step in this process is primary adhesion, or "tethering" which slows the flowing cell by inducing it to roll or bump along the endothelium. After this initial encounter cells may either disengage and be carried away by the flow or, in the presence of the correct triggering factor, undergo secondary adhesion during which binding to the endothelium is stabilized and the leucocyte changes shape, becomes flattened and strongly adherent to the vessel wall. Over the next few minutes the cell migrates between the endothelial cells into tissue, a process termed diapedesis.

Thus, there are four requirements for leucocyte recruitment: (1) tethering or primary adhesion, (2) triggering of strong adhesion, (3) strong adhesion, and (4) transendothelial migration into tissue.

MULTIPLE ADHESION MOLECULES ARE INVOLVED IN LEUCOCYTE BINDING TO ENDOTHELIUM

A number of structurally diverse adhesion molecules, are involved in this adhesion cascade [6, 21] (fig. 4 and table 1). The expression of these molecules is regulated with differentiation and activation both of the endothelium and the leucocyte and is therefore a dynamic process in which both cell types play an active role [97].

Table 1 Some of the molecular pairs involved in leucocyte endothelial adhesion. CHO represents carbohydrate receptors of which there are several. * Expressed on particular subsets of T-lymphocytes. Selectins mediate primary, tethering adhesion

A family of lectin-like adhesion molecules called selectins support leucocyte rolling under flow conditions when they bind to carbohydrate receptors [51]. One of these molecules, L-selectin, is widely expressed on leucocytes. Different leucocytes express distinct forms of L-selectin which can undergo extensive post-translational modification by glycosylation thereby altering receptor specificity. Thus, L-selectin expressed by naive T-cells binds receptors on lymph node endothelium and is involved in the homing of naive cells to lymphoid tissue [73], whereas L-selectin on neutrophils does not mediate binding to lymph node endothelium but instead supports binding to inflamed endothelium.

Two other selectins, E-selectin (CD62E) and P-selectin (CD62P) are synthesized and expressed by endothelial cells after cytokine activation with, for example, IL-1 or TNFα. E-selectin binds to poorly defined oligosaccharide receptors on neutrophils and monocytes and to a subset of CD4+ memory T-cells which express a receptor called the cutaneous lymphocyte antigen [92]. P-selectin is also expressed by activated endothelium and by platelets. P-selectin can be rapidly mobilized from cytoplasmic granules (Weibel-Pallade bodies) to the endothelial cell surface on activation. Although most interest has focused on the ability of P-selectin to mediate neutrophil rolling a subset of T-cells can also bind to P-selectin *in vitro* suggesting a possible role for this molecule in T-cell endothelial interactions [31]. Thus, each selectin recognizes specific carbohydrate sequences and different combinations of receptor and ligand will promote the recruitment of particular leucocyte subsets.

Three properties make selectins ideal mediators of primary adhesion/tethering:

(i) Structure and localization. E-selectin and P-selectin are long molecules that extend out of the surrounding endothelial glycocalyx to make contact with passing leucocytes and L-selectin is concentrated on the tips of leucocyte microvilli where it can best make contact with the endothelial surface.

(ii) Selectins mediate activation-independent adhesion. Leucocytes do not require prior activation to interact with selectins. This is important for an initial adhesive interaction which will take place with a circulating leucocyte that has not yet come into contact with local activating factors.

CP 25788

(iii) Selectins mediate transient and comparatively weak adhesion. This tethering allows the leucocyte to come into contact with the endothelium but to subsequently disengage if further strong adhesion is not triggered [51].

It has recently been reported that other molecules can mediate primary adhesion of lymphocytes [72]. For example, the integrin ligand VCAM-1 can mediate both primary (tethering) and secondary (strong) adhesion [44]. This may be particularly important in low-flow systems such as the lung, liver and spleen. Furthermore, in these systems it is possible that strong, integrin-mediated adhesion can take place without prior tethering.

Triggering of integrin-mediated adhesion by secreted factors

Strong, secondary adhesion to endothelium is mediated by leucocyte adhesion molecules of the integrin family. A characteristic property of integrins is their requirement for conformational activation before optimal ligand binding can occur [42]. Thus, a triggering step is required in the cascade during which integrins are functionally activated to bind to an appropriate endothelial counter-receptor [6].

Trigger factors for leucocytes fall into two broad categories: (i) cell surface molecules, and (ii) cytokines and secreted factors. The former include L-selectin which, in addition to mediating tethering, can also transmit activating signals to leucocyte integrins when engaged by an appropriate receptor [93] and CD31, an adhesion molecule of the immunoglobulin superfamily that is widely expressed on endothelium and on a restricted subset of T-cells. Engagement of CD31 on these T-cells leads to a conformational change in the T-cell integrins LFA-1 and VLA-4 resulting in activation of binding to the endothelial ligands ICAM-1 and VCAM-1 [102]. Despite the above observations it is likely that the most important adhesion triggers are cytokines and secreted factors.

Pro-adhesive factors for neutrophils and monocytes. It has been known for many years that a diverse group of soluble factors can act as chemoattractants for neutrophils and monocytes (table 2). These include bacterial-derived proteins such as the formyl peptides of which f-met-leu-phe (fMLP) is the best known, C5a, a complement component, leukotriene B4, an eicosanoid, and platelet-activating factor (PAF), a product of phosphatidyl choline metabolism [97]. In addition, neuropeptides such as the endorphins have recently been shown to act as neutrophil chemoattractants [114]. As well as promoting chemotaxis many of these factors also activate leucocyte adhesion. Thus, they may play a dual role both as trigger factors and chemotactic factors, thereby promoting transendothelial migration into tissue.

By their nature one would expect the above factors to be released at sites of bacterial invasion or tissue injury. Consistent with this, their actions are largely restricted to cells of the myelomonocytic lineage which are rapidly recruited during acute inflammation. They do not have strong actions on lymphocytes and cannot, therefore, provide all the necessary signals to explain the specificity of leucocyte subset recruitment. The discovery of the chemokine family of chemotactic cytokines has provided the extra options which allow the paradigm to be extended to other leucocytes, notably lymphocytes [24, 97].

Table 3 Structural chemokine families. The C-C chemokines and the non-ELR subfamily of the C-X-C chemokines act predominantly on monocytes, lymphocytes and eosinophils. The ELR C-X-C chemokines act on neutrophils and lymphotactin acts only on lymphocytes (for more details see text and ref.[15]

The role of chemokines in leucocyte subset recruitment. Chemokines are a family of structurally distinct cytokines, that are chemotactic and proadhesive for leucocyte subsets [52, 67, 81]. There are over 30

Table 2 Examples of different soluble factors that can trigger leucocyte chemotaxis. The growth factors described here are also cytokines in that they act on and between cells of the immune system; they have been included in a separate category here because, owing to their potent growth regulatory effects on other cell types, they are more commonly perceived as growth regulators rather than as immune regulators. Likewise, the term cytokines refers to the classic cytokines and excludes chemokines which are shown separately

known human chemokines all of which have a characteristic structure and share sequence homology [15]. They can be divided into three subfamilies based on their structure (see table 3). α- and β-chemokines have two disulphide bonds between a total of four cysteine residues whereas the C chemokines have only two cysteines. The α-chemokines, also known as C-X-C chemokines, are distinguished from β-chemokines or C-C chemokines because the first two cysteine residues from the N-terminal are separated by an intervening amino acid (hence C-X-C) whereas in the β-chemokines they are adjacent (C-C). These structural distinctions are important since they confer on chemokines the ability to act on particular leucocyte subsets (table 4). Thus, most of the C-X-C chemokines which include IL-8 and gro/MGSA act predominantly on neutrophils whereas the C-C chemokines (RANTES, MCP-1) act on lymphocytes, monocytes and eosinophils; lymphotactin, the only C-family chemokine that has been functionally characterized so far acts solely on lymphocytes [48].

Some chemokines, i.e. IL-8 and MCP-1, are widely expressed in cells including platelets, leucocytes, endothelium and epithelium, whereas others have a more restricted distribution. Chemokines are expressed a low concentrations in resting cells but are rapidly upregulated on activation when chemokine mRNA can comprise up to 1 % of total cellular mRNA. The factors that activate cells to secrete chemokines vary depending on cell type, site and chemokine and include pro-inflammatory cytokines such as IL-1, TNFα, gIFN, the bacterial cell wall product lipopolysaccharide and chemical mitogens such as phorbol esters.

All of the chemokines so far isolated bind to a family of G-protein-linked, transmembrane spanning receptors [61]. This family also includes the receptors for fMLP, C5a and LTB4. There are many chemokine receptors with differing ligand specificities.

They can be broadly and conveniently categorized into:

(i) specific receptors that only bind a particular chemokine: for example the IL-8RA receptor only binds IL-8;

(ii) receptors with restricted specificity such as the C-C chemokine receptor CKR-1 which binds most of the C-C chemokines but does not bind C-X-C chemokines and the IL-8 receptor RB which binds C-X-C but not C-C chemokines;

(iii) promiscuous receptors such as the Duffy blood group antigen which is expressed on red blood cells and endothelium and binds all known chemokines.

Engagement of leucocyte chemokine receptors by ligand results in calcium mobilization, phosphokinase C (PKC) activation and cytoskeletal rearrangement within the cell. The functional consequences of this include enhanced migration and conformational activation of cell surface integrins to facilitate binding to ligand. Thus, IL-8 activates β2 integrin-dependent adhesion of neutrophils whereas macrophage inflammatory protein-1β (MIP-1β), the first cytokine reported to trigger T-cell adhesion, activates the T-cell β1 integrin VLA-4 to bind to its endothelial counter-receptor VCAM-1 [100]. Since then several other chemokines have been shown to have such an effect; these include MIP-1α, macrophage chemotactic protein-1 (MCP-1), RANTES and interferon-inducible protein-10 (IP-10) [103].

Why can so many diverse cytokines trigger leucocyte adhesion to endothelium? There are two possible explanations: first, that this function is so crucial to host survival that several mechanisms have evolved resulting in a degree of redundancy. This possibility is being investigated in animal models using antibodies to neutralize particular chemokines and then testing the ability of the animal to respond to an inflammatory stimulus. Recently, mice have been developed in which the gene for a particular chemokine has been deleted. Such knock-out mice will provide valuable insights into the role of individual chemokines. The second possibility is that specificity within the chemokine family is tightly regulated and requires the existence of multiple chemokines to provide the required options. There is some evidence for this and it seems likely that specificity acts at several levels, for instance:

(i) Specificity for leucocyte subsets. If particular chemokines act on specific subsets of leucocytes multiple chemokines will be required to account for

Table 5 Combinations of molecular interactions mediate leucocyte subset recruitment. Each leucocyte can select one of several options at each step in the adhesion cascade. The individual interactions will not necessarily confer selectivity on recruitment but the combination of sequential interactions does. Examples are given for combinations that will result in the selection of distinct leucocyte subsets (for more details see ref. [97])

	Neutrophil	Monocyte	Naive T-cell	Skin memory T-cell

Migration	PAF	MCP-3	MIP-1β	MCP-1

the selectivity of leucocyte recruitment. For example, gro acts on neutrophils but not on eosinophils or lymphocytes whereas RANTES acts on eosinophils and lymphocytes but not neutrophils [48, 82, 83]. Furthermore, there is evidence for preferential activity within T-cell subsets, for instance MIP-1β affects naive T-cells whereas RANTES and MCP-1 affect memory T-cells [4, 100].

(ii) Restricted tissue expression of chemokines. Distinct chemokines are required to recruit cells to particular sites. For example, IL-8 and MCP-1 are expressed by epithelial cells and may have a particular role in recruiting cells to combat invading pathogens at epithelial surfaces.

(iii) Differences are response to activating stimuli. Different chemokines are induced by particular pro-inflammatory cytokines. For example, the secretion of C-C chemokines such as MCP-1 is enhanced by γIFN whereas the secretion of most C-X-C chemokines such as IL-8 is inhibited.

There is evidence that all of these factors are important. However, there is overlap in the actions of most of the chemokines and the specificity of leucocyte recruitment is almost certainly regulated by the combined effects of all the elements in the adhesion cascade rather than by a highly specific chemokine (table 5).

Pro-adhesive factors act as immobilized ligands. In order to trigger adhesion and transendothelial migration effectively, pro-adhesive factors must be available at the vessel wall where they can interact with circulating leucocytes. Immunohistochemical studies have demonstrated chemokine staining on the vessel lumen and the mechanism of their retention in the endothelium has recently been elucidated (fig. 4). Chemokines have glycosaminoglycan binding motifs that allow them to bind proteoglycans in the endothelial glycocalyx and thereby be retained at relevant sites [79, 100, 101]. An extra layer of complexity is provided by recent reports showing differences in the affinity of chemokines for particular proteoglycans. Since endothelial proteoglycans vary between different sites and can be altered in inflammation; this may add to the selectivity of site-specific recruitment [111].

The chemokines that are retained in the endothelial glycocalyx may come from two distinct sources. First, the endothelium itself has the capacity to secrete a range of chemokines on activation, including IL-8 and MCP-1. Alternatively, inflammatory cells, such as monocytes and fibroblasts beneath the endothelium, secrete chemokines that are subsequently transported to and retained in the endothelial glycocalyx.

Another pro-adhesive factor, PAF, is also present at the vessel wall although the mechanism of its retention there is different. PAF is a phospholipid which is produced by endothelial cells within minutes of activation by thrombin, histamine or leukotriene. It is expressed at the endothelial surface but not released into the fluid phase. This endothelial-associated PAF can trigger neutrophil β2-integrin activation and promote transendothelial migration.

Strong, secondary adhesion is mediated by leucocyte integrins that bind members of the immunoglobulin superfamily on endothelium

Integrins are a family of heterodimeric membrane glycoproteins that can be grouped into families based on their β subunit [7, 96]. The most important integrins for leucocytes are the β1- and β2-integrins. The β1-integrins include VLA-4 which is expressed on lymphocytes and monocytes, but not neutrophils. VLA-4 consists of a common β-chain (CD29) paired with the α-chain CD49d. It binds to the endothelial receptor VCAM-1 (CD102). VCAM-1 is absent from most non-inflamed endothelium but is expressed in response to pro-inflammatory cytokines and IL-4. The β2-integrins consist of LFA-1 (β-chain CD18 paired with α-chain CD11a), MAC-1 (CD11b/Cd18) and gp150,95 (CD11c/CD18). LFA-1 is the dominant β2-integrin on lymphocytes but is also expressed on other leucocytes. It binds to two members of the intercellular adhesion molecule (ICAM) family of adhesion molecules, that are expressed on endothelium; ICAM-2 (CD) is constitutively expressed and mediates binding to resting endothelium, whereas ICAM-1 (CD54) expression is increased with activation and predominates in binding to inflamed endothelium [97]. MAC-1 (CD11b/CD18) is the dominant integrin on neutrophils and monocytes. It binds to ICAM-1 on activated endothelium. GP150,95 does not bind directly to endothelium although it can interact with endothelium via its ability to bind fibrinogen [71].

The expression of integrin ligands by activated endothelium at sites of inflammation *in vivo* depends upon the nature of the endothelial-activating stimulus. For instance, both ICAM-1 and VCAM-1 can be induced on resting endothelium by exposure to the pro-inflammatory cytokines tumour necrosis factor α (TNFα), IL-1 and gamma interferon (γIFN) whereas IL-4 selectively induces VCAM-1 expression [84, 91]. Furthermore, there are differences in the adhesion molecules expressed by endothelial cells from different tissues and in their responses to pro-inflammatory cytokines.

Migration

After binding strongly to endothelium the leucocyte migrates between the endothelial cells into tissue in a process called transendothelial migration or diapedesis. As mentioned above, many of the cytokines that trigger strong adhesion can also act as chemotactic factors to promote transendothelial migration [4, 100, 103]. Thus IL-8 induces chemotaxis of neutrophils as well as triggering their adhesion and MIP-1β can induce both adhesion and migration of T-lymphocyte subsets. As discussed below migration is dependent on regulated adhesion and de-adhesion as well as on cytoskeletal rearrangement within the cell and it is not therefore surprising that these properties are frequently shared.

COMBINED EFFECTS OF SEQUENTIAL INTERACTIONS DETERMINE LEUCOCYTE SUBSET RECRUITMENT

The adhesion cascade provides a powerful model for controlling the specificity of leucocyte subset adhesion to endothelium that can be both rapidly amplified and carefully controlled. Specificity and regulation can be introduced at each of the sequential interactions giving rise to the paradigm proposed by Butcher and Springer of "area codes" for leucocytes [24, 97]. Thus, a particular leucocyte will have several options at each step of the cascade and it is the combined effects of the interactions that will determine the specificity of recruitment.

Regulation of leucocyte adhesion—physiological control *vs* pathological disorder

MULTI-STEP ADHESION IS A CONTROL STRATEGY THAT MAY BE SUBVERTED

Circulatory and molecular considerations outlined above suggest that selectin-mediated rolling adhesion is a prerequisite for leucocyte immobilization because it allows pick-up of localized signal(s) and because, for neutrophils at least, immobilizing integrin-mediated attachment cannot operate rapidly enough to capture flowing cells. However, multi-step adhesion is not an absolute necessity in the sense that lymphocytes can be immobilized by a single integrin–immunoglobulin interaction [11] and that parasitized red cells can be immobilized by endothelial receptors directly from flow [29]. This suggests that rolling is part of an evolved control strategy rather than a physical necessity, and that signalling is the limiting process in multi-step adhesion. With rolling itself dependent on an endothelial response to stimulus, and neutrophil stabilization dependent on pick-up of signal from the endothelium after initial attachment, several controllable responses must occur in order to complete immobilization.

Even then, further regulated steps must underlie onward neutrophil locomotion (which requires continual modulation of adhesive interaction to allow detachment at the rear of the cell and new attachment at the front), and migration in a preferred direction. The concept that neutrophils can move along a concentration gradient of chemoattractant is well established [27], and one can foresee the existence of such a gradient in connective tissue containing an inflammatory stimulus. However, it is not clear how a gradient could be established in the presence of flowing blood, and so it seems that the neutrophils move across the surface and between endothelial cells along some other guideline. Taken together, migration requires a sequence of events and transformations, open to control at each stage and dependent on incompletely understood signalling responses. It is not surprising that multiple regulatory steps exist because, for instance, if neutrophil adhesion and migration were to proceed without tight control, then the potential for amplification of a catastrophic inflammatory reaction would be great. This raises the question as to whether pathological events follow a similar pattern and rely on the "normal" control sequence or whether various of the regulated steps are missing or out of order, bringing about uncontrolled and potentially damaging leucocyte–endothelial interaction.

KINETICS OF TRANSFORMATIONS IN THE MULTI-STEP SEQUENCE MAY BE CRITICAL FACTORS IN ITS OUTCOME

If the multi-step process represents a strategy for controlling adhesion and migration, then the rate at which transformation between steps occurs will have a critical influence on the outcome. As noted above, capture of flowing blood cells requires a fast-acting adhesive interaction, but the kinetics of transformation to stable attachment may also be important. Several studies now show that initial tethering events may be short-lived and leucocytes may only make brief initial contact with endothelium, especially if receptors such as selectins are expressed at low level [10, 16]. This may be an advantage, in that if signals are not present, the tethered leucocytes will be swept away. It does imply, however, that signalling and leucocyte responses must be rapid for immobilization to be achieved. Indeed, recent studies show that short-lived interactions can underlie successful, signal-dependent immobilization of lymphocytes in lymph nodes [16], and our own observations indicate that neutrophils can respond to adhesion-promoting, activating stimuli in seconds and probably even more rapidly [76, 90]. When rolling adhesion is more long-lived, there may not appear to be a necessity for such rapid signalling, but if leucocytes are to be localized accurately, then they must still come to a halt within a short distance of exposure to stimulus.

Clearly this can only be achieved by localizing the stimulus, i.e. as noted above, on the cell surface rather than relying on the fluid phase. Moreover, failure to localize the stimulus or the cell response would lead to undesirable dispersal of active cells or mediators into the systemic circulation.

After immobilization of leucocytes on the endothelial surface, transformation to migration might be able to occur at a more leisurely pace. However, its successful completion is necessary because otherwise the vessel lumen is in danger of occlusion, and because the immobilized neutrophil contains an arsenal of lytic enzymes, has great oxidant potential and is capable of producing mediators which could attract further leucocytes to the site. In fact, it is unclear how activated neutrophils order such events. *In vitro* stimuli tend to induce oxidative bursts, degranulation and release of mediators along with pro-adhesive changes. *In vivo*, adhesion must come first, followed by migration, and then the destructive potential needs to be unleashed on contact with foreign bodies or necrotic tissue. Thus, there must be a lag of the order of minutes and a dissociation of the responses that is not always evident *in vitro*. We have seen very high levels of neutrophil attachment and migration on cytokine-stimulated endothelial cells without apparent damage to the monolayer (unpublished observations), so that some form of "pathological" priming such as hypoxia may be required to induce neutrophils to cause endothelial damage [43]. Control and localization of the neutrophil lytic response might come about through some endothelial regulatory factor (such as nitric oxide) and it may be that stimulation protocols used for neutrophils in suspension *in vitro* do not mimic the situation when initial stimuli are presented on the endothelial surface.

Adhesive leucocytes must thus clear the vessel lumen before proceeding to other functional responses. Otherwise obstruction in the lumen could be amplified by neutrophil–neutrophil interaction, such as homotypic aggregation and transfer of activating agents such as PAF and Il-8. At high levels of neutrophil adhesion in *in vitro* flow models we have found evidence of activated adherent cells forming contacts and building quite large aggregates if they cannot transmigrate [G. E. Rainger, G. B. Nash, unpublished observations]. Thus, uncontrolled adhesion could lead to impaired perfusion and intravascular damage if neutrophils do not migrate, as well as destruction of surrounding tissue if they do.

DO PATHOLOGICAL EVENTS FOLLOW THE PHYSIOLOGICAL SEQUENCE?

The foregoing suggests two main possibilities: that pathological adhesive interactions follow a normal controlled sequence, but that they occur at an inappropriate or undesired time or over a prolonged period; that disordered or unregulated processes lead to uncontrolled build up of leucocytes and tissue damage, for example if activation occurs before immobilization or cells fail to complete the full response. In fact, both scenarios are likely *in vivo*. Although rolling, signalling, stopping and migration may occur in sequence (perhaps after hypoxia and reoxygenation judging from *in vitro* studies [75]), steps might be missed out under special circumstances. The necessity for selectin-mediated adhesion might be lost, for example, under low-flow conditions where activated integrins would be able to immobilize neutrophils directly [70], or in tissues with unusual architecture or flow pattern, such as the lungs. Moreover, the initial step might be mechanical rather than adhesive. Impaired neutrophil deformability is associated with number of ischaemic disorders [62, 64, 65], smoking [89] and circulating antineutrophil cytoplasm antibodies associated with autoimmune vasculitis [25]. Loss of deformability has been shown to be capable of causing trapping of neutrophils in the lungs independent of adhesion [112], and so adhesive and damaging interactions could follow on from mechanical changes without initial endothelial exposure of tethering molecules. Moreover, it may not be correct to treat mechanical and adhesive responses as separate, because the time courses of each are similar (rapid initial phase in seconds, followed by modulation over minutes), and there is evidence that skeletal structures within the cell regulate adhesive behaviour [46].

The concept of out-of-order adhesion is not so well documented, although it is known that if eosinophil integrins are "frozen" in an activated state the cells can no longer migrate [50]. Successful neutrophil immobilization seems to rely on activation of constitutive integrins while migration requires integrin deactivation and successive waves of new integrin expression and activation [41, 90]. Disruption of this sequence might interfere with its continuation. Activated neutrophils bind to resting endothelial cells but show little migration compared with neutrophils bound to cytokine-treated endothelium (unpublished observations), so that activation of only one side of the leucocyte–endothelial interaction results in an incomplete response. As noted above, the phagocytic and lytic responses of leucocytes need to occur at the right time, and there is the hypothetical possibility at least that pathology can arise if they are induced before migration. Compared with the current quite extensive knowledge of adhesion molecules themselves, the regulation of transformations (rolling to stopping; stopping to migration; migration to phagocytosis/degranulation) is an outstanding puzzle, and its manipulation may be a route to achieving control of inflammation.

DO OTHER CELL–CELL INTERACTIONS INCREASE THE PATHOLOGICAL POTENTIAL OF ADHESION BETWEEN LEUCOCYTES AND ENDOTHELIUM?

Adhesion of leucocytes to endothelium may be the primary promoter of vascular pathology, but there are other forms of intercellular interaction with "physiological" or "pathological" potential that are worthy of comment (fig. 5). As noted previously, monocyte/macrophages provide cytokines and chemokines which can activate endothelium, neutrophils and lymphocytes. Less well recognized is the

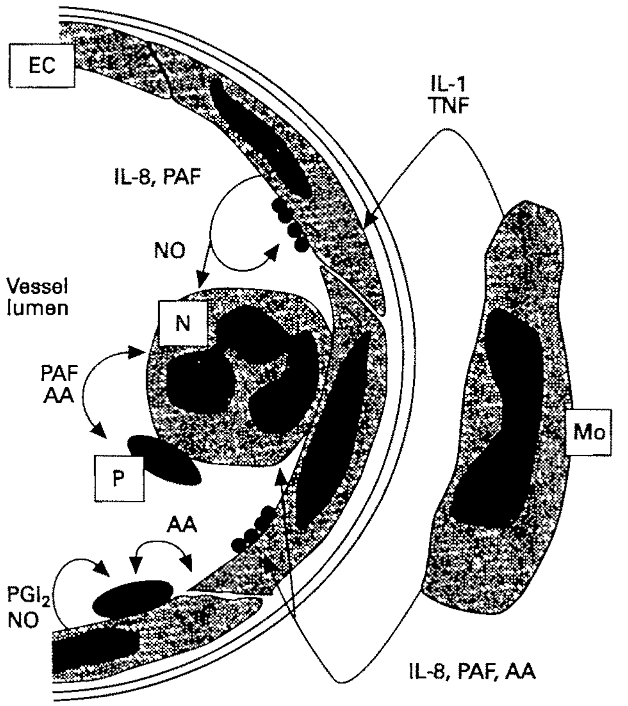

Figure 5 Cell–cell interactions that may potentiate or regulate adhesion of neutrophils (N) to vascular endothelial cells (EC). Endothelial cells manufacture and present the activating signals IL-8 and platelet-activating factor (PAF), and the regulatory factor nitric oxide. Arachidonic acid and its metabolites may be exchanged between neutrophils, endothelial cells, platelets (P) and monocytes (Mo). Monocytes manufacture IL-8 and PAF, as well as cytokines (TNF and IL-1) which activate endothelial expression of adhesion molecules. Platelets can present an additional adhesive surface for neutrophils, a process probably inhibited by nitric oxide (NO) and prostacyclin (PGI_2) from endothelial cells. Activated components of complement (e.g. C5a) may be derived from surrounding tissue, e.g. after hypoxia.

likelihood that platelets modulate the inflammatory response. Platelet attachment to sub-endothelial matrix is an essential part of haemostasis. However, they can also bind to leucocytes in blood and can act as an adhesive surface for flowing leucocytes [26, 78], interactions of uncertain physiological function. Immobilized platelets support both rolling attachment of unstimulated neutrophils and stationary attachment of activated cells [26, 90]. In addition, platelets and neutrophils are capable of releasing factors which activate each other and the response of each to stimulus is greater in the presence of the other, for example because of their capability to exchange metabolites of arachidonic acid (eicosanoids) and because of release of neutrophil granule enzymes (see ref. [63] for review). Thus, one may predict that co-localization of platelets and neutrophils would amplify the inflammatory response, and evidence from animal models suggest that reperfusion injury and thrombosis in vessel grafts are indeed augmented by their interaction [58, 68]. It may also be worth noting that biochemical interactions may be three-cornered, including the endothelial cells which release factors modulating platelet response (e.g. prostacyclin and nitric oxide) but can also participate in exchange of metabolites of arachidonic acid with platelets and neutrophils [56].

Interaction between leucocytes may also occur within the lumen. Homotypic aggregation between neutrophils occurs after stimulation in purified suspensions and in blood, and is associated with agents such as activated components of complement (e.g. generated during haemodialysis) [30, 49]. The mechanism of aggregation appears to involve both integrin- and selectin-mediated adhesion [94]. If an immobilized neutrophil acts as a focus for attachment of others flowing past, then the potential for vascular occlusion is great; alternatively, aggregates formed in the blood would block small vessels directly. The circulatory conditions under which such interactions occur and the molecular mechanisms appear worthy of further attention.

Leucocyte–endothelial interactions and disease

Leucocyte–endothelial interactions are vital for effective host defence against pathogens and when they fail overwhelming sepsis can result. This is best illustrated by two rare inherited disorders—leucocyte adhesion deficiency type 1 (LAD-1) and type 2 (LAD-2) that are associated with deficiency of CD18 and sialyl Lewis X respectively. Both syndromes result in dramatically reduced neutrophil recruitment to sites of inflammation and are associated with recurrent life-threatening sepsis.

In addition to their role in protecting the host, leucocyte–endothelial interactions can contribute to the generation of unwanted, pathological inflammation in such conditions as reperfusion injury after ischaemia, septic shock, autoimmunity, allergic responses and allograft rejection. For example, pulmonary infiltration as part of the adult respiratory distress syndrome (ARDS) is a serious complication of septic shock resulting from acute pancreatitis. Although the original focus of disease is distant from the lung, neutrophils are inappropriately recruited to the pulmonary bed because of enhanced adhesion to the pulmonary microvasculature. The increased adhesion of leucocytes to microvasculature in the liver, lung and kidney is a crucial factor in the development of MOF in septic shock and, as discussed above, results from increased rigidity and inappropriate activation of adhesion molecules on circulating leucocytes [37] or from activation of the endothelium by circulating factors such as endotoxin or LPS [23]. The role of leucocyte adhesion to endothelium in this setting is demonstrated by the fact that the development of ARDS can be inhibited by the administration of antibodies to block CD18 or the use of oligosaccharides that block leucocyte binding to selectins [59]. In addition, mice that are genetically deficient in ICAM-1 are resistant to the fatal complications of septic shock [22].

Increased expression of endothelial adhesion molecules is associated with a range of inflammatory disorders from graft rejection to liver cirrhosis [21]. Acute inflammatory disorders are associated with infiltration by neutrophils and tend to be accompanied by increased expression of E-selectin and P-selectin whereas in chronic, lymphocytic inflammation ICAM-1 and VCAM-1 expression predominate. Thus, E-selectin is strongly expressed on endothelium in acute appendicitis and is found in high concentrations in the circulation in septic shock, whereas VCAM-1 is induced during the chronic inflammation of sarcoidosis and graft rejection, conditions associated with a lymphocytic infiltrate [66]. However, these distinctions are often less clear-cut and E-selectin, ICAM-1 and VCAM-1 may be expressed together at sites of chronic inflammation. However, caution should be used when interpreting studies based on increased expression of adhesion molecules [74]. The presence of a particular adhesion molecule does not always imply it has a functional role in that particular clinical setting. For example, E-selectin is upregulated on endothelium in the chronic immune-mediated liver disease, primary biliary cirrhosis, suggesting it is important for the generation of the chronic inflammatory infiltrate. However, very few of the infiltrating leucocytes in this disease express receptors capable of binding E-selectin suggesting that E-selectin expression in this disease is a consequence of the local inflammation and of no direct relevance to leucocyte recruitment [8].

There are now accumulating data on chemokine expression in a number of inflammatory diseases. Transplant graft rejection is associated with increased tissue expression of RANTES, ENA-78, MIP-1α and MIP-1β [2, 69, 86] and a wide range of other immune-mediated diseases have been associated with increased chemokine expression and secretion [19, 40, 77, 87, 95]. The ability of IL-8 to trigger neutrophil recruitment suggests it will be involved in the inflammatory response of sepsis and several studies have shown increased circulating IL-8 in patients with septic shock [57]. In addition, anti-IL-8 treatment can ameliorate some of the features of sepsis in animal models. It has recently been suggested that MIP-1α also plays a crucial role in septic shock and it is likely that a network of chemokines will be involved in this complex disease [55, 98].

Thus, in order to understand the pathogenesis of an inflammatory response one requires a detailed understanding of the dynamic regulation of all elements in the adhesion cascade.

SOLUBLE ADHESION MOLECULES IN INFLAMMATION

Many cell surface adhesion molecules are shed into the fluid phase in response to cellular activation [66, 80]. These include the leucocyte adhesion molecules L-selectin and CD31 and the endothelial adhesion molecules ICAM-1, VCAM-1 and the selectins. The functions of soluble adhesion molecule release are not known. There is evidence that soluble E-selectin can activate neutrophils suggesting it might act as an inflammatory mediator [53]. Alternatively other groups have suggested that soluble adhesion molecules are a homeostatic mechanism to block adhesion and downregulate inflammatory responses [35]. Whatever their functional significance soluble CAMs are markers of inflammation in a range of acute and chronic inflammatory disorders [3, 5, 35]. However, few studies have shown any great prognostic or diagnostic advantage in measuring adhesion molecules compared with other markers of inflammation.

THERAPEUTIC IMPLICATIONS

The recent advances made in understanding the molecular basis of leucocyte–endothelial interactions suggest new approaches for therapeutic intervention in a range of inflammatory diseases [1]. Monoclonal antibodies that block the function of particular adhesion molecules have been used to prevent tissue infiltration by leucocytes in animal models. For example, antibodies to E-selectin prevent antigen-induced airway hyper-responsiveness in a primate model of asthma by inhibiting neutrophil infiltration and in models of reperfusion injury antibodies to ICAM-1 and CD18 have successfully reduced tissue infiltration and damage caused by neutrophils [18, 36, 47, 110]. In addition to therapy aimed at blocking acute inflammation other studies have addressed the treatment of chronic immune disorders. Antibodies to VLA-4 reduce T-cell infiltration into the brain and slow disease progression in a rat model of multiple sclerosis suggesting that anti-adhesion molecule therapy might prove beneficial in autoimmune diseases [17, 113].

Clinical trials of anti-adhesion molecule therapy are few; antibodies to ICAM-1 have shown only limited promise in the treatment of graft rejection and rheumatoid arthritis and the use of murine monoclonal antibodies to treat chronic autoimmune diseases is complicated by the development of neutralizing anti-murine antibodies [32, 39]. The development of humanized or chimeric antibodies overcomes the latter problem but other treatments based on molecular analogues have many pharmacological advantages. Such therapy has recently been tested in animals. Peptides that bind to and block the function of the leucocyte integrin Mac-1 (CD11b) have been used to reduce neutrophil infiltration and tissue damage in bacterial meningitis [105]. Infusions of oligosaccharides containing sialyl-Lewis X, the carbohydrate ligand for P-selectin and E-selectin, prevented neutrophil-mediated lung injury induced by injections of cobra venom, a model with many features that are similar to ARDS [60].

More recently, therapy aimed at blocking chemokines has been tested in animal models of inflammation. Anti-MCP-1 treatment prevents the development of granulomatous lung disease in a murine model [54] and anti-IL-8 treatment reduces reperfusion lung injury [88].

It is likely that the next few years will see the development of new therapies to prevent leucocyte–endothelial interactions by directly inhibiting the adhesion molecules involved or by modulating their regulation by inhibiting cytokine-induced signalling in endothelium or blocking the actions of the chemokines that trigger leucocyte adhesion molecules. However, the complexity of the processes involved suggests that simple approaches to therapy are unlikely to be successful and that blocking a particular molecule may have consequences that were initially unforeseen. It is thus essential that such studies are investigated and set up in the context of the adhesion cascade and tested thoroughly before being applied to clinical disorders such as septic shock.

Molecular mechanisms of drug metabolism in the critically ill

G. R. PARK

Drugs are used in every critically ill patient. Despite this, our knowledge of how drugs behave in these patients has, until lately, been limited. It has been based on information obtained from animals, volunteers, relatively fit patients or others in a stable phase of a chronic disease. Ethical, logistical, financial and the confounding effects of disease have delayed the understanding of drug metabolism in this group of patients. Although these difficulties are now being overcome the advent of isolated cell systems and molecular biological techniques are answering questions that could not be answered by studying patients. Indeed, these techniques will not only help solve some of these problems, they will help prevent others with new drugs. Already drug interactions can be predicted before a drug is marketed. In addition, new drugs are now being designed not to use routes of elimination likely to fail in the critically ill.

Drug metabolism is not static but dynamic. It can be expected to change as the patient's condition worsens or changes. This is illustrated by one patient in septic shock who was given a continuous infusion of midazolam (fig. 1). At first there is a rapid increase in the concentration of midazolam, with little or no production of the metabolite because the enzymes are "sick". As his condition (and that of the enzymes) improves (day 4) metabolite appears in the blood. On day 13 he develops a nosocomial pneumonia and again the enzymes become "sick" and the production of metabolite is reduced [135].

Metabolism

Drugs are usually metabolized through several pathways, the aim being to change fat soluble, active, unexcretable drugs into water soluble, inactive drugs that are able to be excreted by the kidneys and in the bile.

Two phases of metabolism are usually involved. The first is phase I metabolism, that commonly involves the cytochromes P450 (CYP), performing reactions such as oxidation and hydroxylation. Other phase I reactions, involving other enzymes also occur (table 1).

The metabolites these enzymes produce may be less active or highly reactive and even toxic. For example, when paracetamol is metabolized by phase I metabolism, the metabolite, *N* acetyl-*p*-benzoquinone (NAPQI), causes hepatotoxicity. Usually the phase I metabolite is metabolized further by a phase II enzyme that conjugates it with another group such as glutathione, a glucuronide or a sulphide group. A typical example of a drug going through both phase I and phase II metabolism is midazolam. It is metabolized first to 1-hydroxy midazolam and then to 1-hydroxy midazolam glucuronide.

Some drugs are metabolized mostly by phase II metabolism. An example of this is morphine, that is metabolized to morphine-3 glucuronide (M-3G) and morphine-6 glucuronide (fig. 2).

It should be noted that many drugs have several pathways. Indeed, drugs may switch between pathways. In one study [71] rats were infected with malaria and then given low and high doses of paracetamol. Compared with uninfected rats there was little change in the clearance of paracetamol, but there was a decrease in glucuronidation compensated for by an increase in sulphation. At high doses sulphation was saturated and clearance reduced.

Cytochromes P450 and other phase I enzymes are generally present in smaller amounts than phase II enzymes and they are more affected by disease. If they are reduced in amount the metabolite for phase II metabolism will not be made and the drug will not be metabolized. Thus, the amount and function of phase I enzymes are usually the rate limiting step in drug metabolism.

Cytochromes P450 are a family of haemoproteins. About 25 have been described in humans: they are characterized by their amino acid homology. Families are identified by an Arabic number and have at least 40% amino acid homology. The subfamily is identified by a capital letter and has at least 55% amino acid homology [106]. The gene product is identified by a further Arabic number. This nomenclature has superseded the classification based on substrate specificity. It allows recognition that cyclosporin oxidase and nifedipine oxidase are an identical enzyme; cytochrome P450 3A4.

The cytochromes P450 are ubiquitous. The highest *concentrations* of these enzymes are found in the nose (where they break down the amines that cause smell) and in the adrenal gland (where they produce steroids). The greatest *mass* is found in the liver. They have many functions besides the metabolism of xenobiotics. They are important in the regulation of the body, making steroids of all types. Furthermore,

Xanthine oxidase

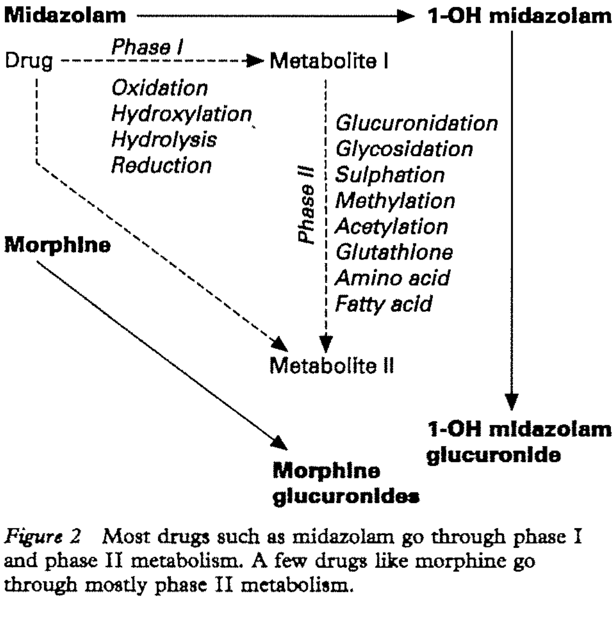

Figure 2 Most drugs such as midazolam go through phase I and phase II metabolism. A few drugs like morphine go through mostly phase II metabolism.

their study is of great importance in understanding carcinogenesis since, for example, it is these enzymes that produce carcinogens from cigarette smoke.

Three enzymes are of major importance in understanding drug metabolism for anaesthetists, others are shown in table 2. Cytochrome P450 2D6 has polymorphic expression and does not function in 10% of the population. Cytochrome P450 2E1 produces many reactive metabolites. Mention has already been made of paracetamol, but this cytochrome also metabolizes volatile agents again producing reactive metabolites. Cytochrome P450 3A4, comprising about 60% of all of the cytochromes in the body, metabolizes many drugs used in the critically ill patient.

Some of the drugs used in the critically ill and the enzymes that metabolize them are shown in table 3.

A third group of enzymes is becoming increasingly important for drug metabolism. These are the blood and tissue esterases. The importance of variations in butyryl cholinesterase (pseudocholinesterase) has been appreciated for some time because of its role in metabolizing suxamethonium. Currently, drugs are being designed to go either through butyryl cholinesterase or other esterases similar to it. Mivacurium, a non-depolarizing neuromuscular blocking agent is also metabolized by butyryl cholinesterase and suffers from the same difficulties in metabolism as suxamethonium [111].

Remifentanil, a new opioid, is metabolized by many esterases found both in the blood and elsewhere. This new opioid, because it is metabolized by so many different blood and tissue esterases, is unlikely to be affected by disease or genetic variation, as are suxamethonium and mivacurium. This also makes remifentanil's metabolism independent of liver function. Studies during the anhepatic period of liver transplantation have shown its elimination to be normal [105].

Since the body metabolizes many thousands of compounds every day and has far fewer enzymes, each enzyme metabolizes many substrates. Only very rarely, if ever, will one enzyme only metabolize one substrate.

Changes in enzyme function in the critically ill

Many things change enzyme function. Some of these are shown in figure 3.

Mechanisms for enzyme induction are poorly understood, unlike inhibition, which has been better studied. Generally, inhibition is a fast process while induction is slow. This is because induction results in an increased amount of enzyme in the cell; it usually takes about 24–48 h for this to occur [9]. Some of the mechanisms controlling the amount of enzyme are shown in figure 4.

Some of the common cytochrome P450 inducers and inhibitors are shown in table 4.

Inhibition is usually quick, occurring sometimes after one dose of the inhibitor. It may occur because of changes in the expression of the enzyme, changes in the environment of the cell or because of direct interference with the enzyme itself. For example, there may be substrate competition, illustrated by the combination of erythromycin and midazolam, commonly used in the critically ill patient. The erythromycin prevents the metabolism of midazolam by cytochrome P450 3A4 [67], leading to prolonged coma. There may also be metabolite inhibition of an

Table 2 Various cytochromes P450 (from ref. [29] and elsewhere)

CYP 1A1	This is not expressed constitutively in the liver. It is induced by a variety of substances including omeprazole and cigarette smoking and may be implicated in causing cancer. Other environmental changes may also induce it.
CYP 1A2	Expressed constitutively. Its expression may also be changed by diet or other habits.
CYP 2A6	Constitutively expressed. It is responsible for 7-hydroxylation of steroids and cholesterol to bile acids.
CYP 2C8-2C9	Constitutively expressed. Responsible for the metabolism of tolbutamide, phenytoin (2C19), diazepam and the oxicam NSAID.
CYP 2D6	This cytochrome is subject to polymorphic expression. Debrisoquine, morphine, its analogues and β-blockers are metabolized by it.
CYP 2E1	Constitutively expressed. It metabolizes small molecules including volatile anaesthetic agents, alcohol and other hydrocarbons. This cytochrome is found in the centrilobular region of the liver, the most hypoxic area.
CYP 3A4	Of all the CYP this is the most prolific in human liver. It also metabolizes several drugs commonly used in critically ill patients.
CYP 4A	It is important in many endogenous control pathways. Its expression is controlled by dietary status especially, fats.

enzyme, such as is caused by the antidepressant nortriptyline [104]. Its phase I metabolite inhibits the enzyme that produces it. More recently Cheng and colleagues have shown that propofol may inactivate cytochromes P450 [28]. The importance of this has not yet been shown in humans, but if their *in vitro* results apply to humans then delay and elimination of several drugs might be expected. These and other mechanisms are shown in table 5.

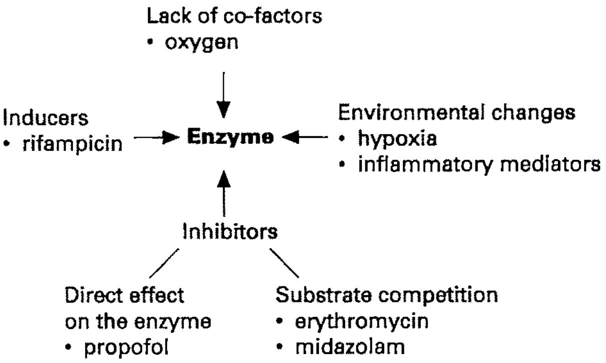

Figure 3 Some of the factors that may change enzyme function.

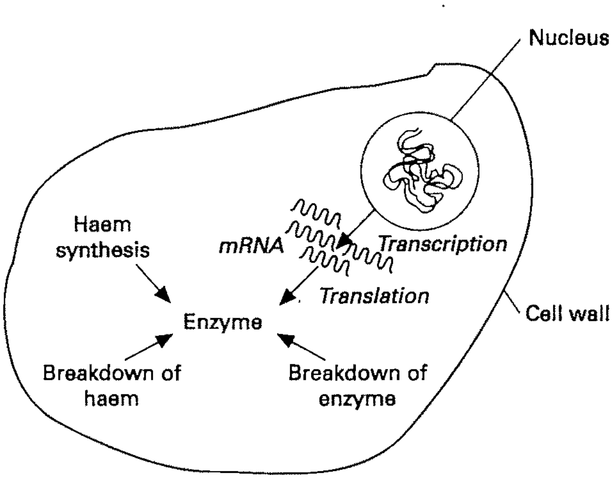

Figure 4 Some of the sites in the cell where different factors may control the amount of enzyme present in the cell [33, 52]. Changes in all of these steps have been described for induction, but not inhibition, of the enzyme.

GENETIC FACTORS

Although interspecies differences in the metabolism of drugs are known about [11] differences within species are less well recognized. However, these can be just as pronounced. In the mouse, sleeping time after hexobarbitone administration varies from 18 (SD 4) min in the SWR/HeN mouse to 48 (4) min for the A/NL mouse, purely because of the variation in enzyme function [52].

In humans even more striking differences exist for the metabolism of suxamethonium. This is metabolized by butyryl cholinesterase which is under the control of several genes. The commonest gene is E_1^u. The various phenotypes and most genotypes can be differentiated on the basis of inhibition of cholinesterase by dibucaine (E_1^a) and fluoride (E_1^f). The silent gene (E_1^s) occurs when the organism is in the homozygous state and so cannot be inhibited. The heterozygote state has normal dibucaine and fluoride inhibition, but reduced cholinesterase function (table 6).

Another important enzyme that is subject to genetic polymorphism is CYP 2D6. Several variants of this enzyme have also been described [69]. Originally, debrisoquine metabolism was noted to be affected by the abnormalities of this enzyme. However, this enzyme also metabolizes codeine to morphine. Because of this, in the 10% of the population who lack functioning CYP 2D6, codeine may be a poor analgesic.

Enzyme changes in the critically ill

Enzymes tend to be thought of as "black boxes". The drug goes in and the metabolite comes out, but enzymes are proteins and just as plasma concentrations of albumin decrease and those of alpha-1 acid glycoprotein increase in response to stress, so intracellular concentrations of enzymes also change.

There is now an increasing amount of information about how enzymes change in response to *one*

stimulus. It is important to remember that usually several stimuli exist at the same time in each patient.

HYPOXIA

The liver is particularly sensitive to hypoxia because 70% of its blood supply is from the portal vein which has blood with a low oxygen content. The remaining 30% is from the hepatic artery. This leads to large differences in the oxygen supply in different parts of the liver. Those near the arterial supply having a high concentration of oxygen and others having a low concentration. These hepatocytes are especially sensitive to hypoxia. Small reductions in hepatic blood flow or blood oxygen concentration will result in these cells becoming ischaemic [138]. This explains the frequency with which ischaemic hepatitis is seen [53].

Oxygen is needed by the cell to metabolize drugs efficiently for several reasons. It is used to produce energy needed both for the reactions themselves and also to make the enzyme. Oxygen is also needed as a substrate for drug oxidation, as a terminal electron acceptor and for processes dependent on the oxidation equilibrium (redox potential of the cell).

Animal work shows that the lowest fractional concentration of inspired oxygen ($F\text{I}_{O_2}$) that a rat who has been given phenobarbitone to induce its enzymes can survive is 0.07. However, liver damage occurs at this concentration. At an $F\text{I}_{O_2}$ of 0.06 the rats start to die and in the survivors liver damage is greater. Although hepatocytes survive in oxygen tensions as low as 0.1 mm Hg ischaemic hepatocytes will not function normally [5] and oxygen tension of 2–10 mm Hg (3–14 μmol litre^{-1}) is needed for energy production.

Although a reduction in $F\text{I}_{O_2}$ will cause hypoxia so too will shock, because of the reduction in blood flow, and consequently oxygen, to the liver. Shock may result from many causes including trauma and myocardial infarction. Both are associated with a reduction in metabolic activity [48]. A German group [48] measured the amount of CYP from a needle biopsy in patients dying with and without shock after myocardial infarction. They also measured the steady state plasma concentration of lignocaine after an infusion. They found patients with shock had a higher plasma concentration (showing a reduced clearance) but the plasma concentration decreased when they were given dobutamine to increase cardiac output. Many mechanisms are involved in the decreased ability of shocked patients to metabolize drugs; a reduction in liver blood flow with resulting hepatic hypoxia is one of these.

Some enzymes are more tolerant of hypoxia than others. Those found in acinar zone 1 (sulphation) are less sensitive to hypoxia than those found in zone 3 (oxidation). Furthermore, cytochrome P450 2E1 is concentrated in the pericentral region of the lobule, the most hypoxic [150]. Thus changes in the oxygen gradients may be expected to change metabolic pathways for drugs metabolized by several enzymes [76].

The time taken for hypoxia to induce changes in drug metabolizing enzymes appears to be short. One study [35] found that rabbits exposed to a low $F\text{I}_{O_2}$ had changes in the ability of their liver enzymes, to metabolize theophylline within 8 h.

When we exposed isolated human hepatocytes in primary culture [117] to hypoxia for 4 days there was a 5–10-fold reduction in cytochrome P450 3A. This was not thought to be caused purely by cell asphyxia because cytochrome P450 2E1 was less affected. The mechanisms surrounding changes in the amount of enzyme in cells are poorly understood. However, substances, such as hypoxia inducible factor I, are being identified to be responsible for the transcription of the human erythropoietin gene [154]; and other similar factors may exist for other genes.

Studying the effects of acute hypoxia in intact animals is difficult because of the various compensatory changes that occur in the cardiovascular system. Increases in cardiac output and changes in regional blood flow will attempt to minimize the decrease in $F\text{I}_{O_2}$. To overcome these difficulties the isolated perfused liver has been used as a model to study the effects of hypoxia on the liver. In this model the concentration of oxygen, carbon dioxide and other nutrients can be controlled precisely. In addition, flow rates can also be changes. Using this model the importance of hypoxia on propranolol clearance has been shown [40, 41].

The changes caused by hypoxia will be worsened if drugs are given that increase cellular oxygen demands. One such group of drugs are the enzyme inducers. Becker and colleagues [14, 15] have shown the effect of inducing hepatic enzymes with phenobarbitone and the subsequent oxygen consumption of hepatocytes isolated from these animals. In the induced state, oxygen consumption increases with both volatile and i.v. anaesthetic agents. Some of these effects returned to normal when a cytochrome P450 inhibitor, metapyrone, was added to the incubates.

Current practice in the shocked patient is to restore cardiac output and improve oxygen delivery. A useful adjunct to this in the future might also be to choose drugs that do not increase cellular oxygen demands.

Liver preservation

Liver transplantation is becoming increasingly common and is one of the most extreme forms of hypoxia. How the liver metabolizes drugs immediately after it has been rendered anoxic, cooled and subjected to two operations has not been well studied. We have studied the metabolism of morphine [136], alfentanil [137] and midazolam [134], and others have looked at glucuronidation [152] and shown that they are metabolized almost normally. Still other workers have studied antipyrine [96]. In one study in rats the ability of livers removed and then stored using hypothermic preservation were compared by their ability to metabolize morphine, fentanyl and vecuronium in livers removed and studied immediately. No difference between the two groups could be found [80]. Thus, the hypoxic insult to the liver caused by transplantation does not appear to cause significant damage to the enzymes.

SYSTEMIC INFLAMMATORY RESPONSE SYNDROME (SIRS)

This term is used to describe the body's response to various injuries [21] and is discussed elsewhere. SIRS affects most of the body, rather than a single organ. Inflammation is an essential part, sepsis with positive microbiological cultures is not essential.

In rats, experimentally induced inflammation has been shown to depress drug metabolism; however this is not reversed by anti-inflammatory agents [13]. Many inflammatory mediators have been described. The ones that are known to have an effect on drug metabolism are interleukin 1(IL-1) [1, 45, 51, 88, 145], interleukin 6 (IL-6) [1], tumour necrosis factor [1] and interferon [31, 32, 38, 50, 99, 102, 118, 125]. The release of many of these may be triggered by endotoxin, itself an important cause of changes in drug metabolism [37, 51, 101, 128, 132].

The inflammatory mediators appear to be essential for survival after infections. When mice were bred to be deficient in the IL-6 gene, they were unable to control infections with vaccinia viruses and *Listeria monocytogenes* [85]. Infecting mice with *Listeria monocytogenes* reduces the expression of some cytochromes P450 and their associated mRNA, taking 96 h to return to normal [6]. Infections release endoxin, and 15 years ago Egawa and colleagues [37] showed that the plasma of mice given endotoxin contained a substance that reduced the amount of cytochrome P450 and its activity. Morgan [101] also showed that in rats given endotoxin there was a reduction in liver cytochrome P450 and also in mRNA. However, a variety of other mechanisms maintained the enzyme, resulting in a proportionally lower reduction in protein than in mRNA. Others have shown similar changes after mice were given IL-1 [132].

Information about human responses to individual inflammatory mediators is limited. Most of the information has been gained from isolated, human hepatocytes grown in primary culture. We used this method to show that serum from five critically ill patients (APACHE score [82] > 15) contains a substance that interferes with the metabolism of progesterone [113, 117]. Since it was unclear whether the serum might be affecting expression of the enzyme in the cells or having a direct inhibitory effect on the enzyme, we did a further study. In this we isolated microsomes (part of the endoplasmic reticulum) containing the cytochromes P450. Midazolam (a CYP 3A4 substrate [87]) was then incubated with the microsomes and serum. Again, the serum was shown to have an inhibitory effect [115]. Although this might explain our earlier observation suggesting the serum contained a substrate that directly inhibits the enzyme, Abdel Razzik and colleagues [1] in Paris, using human hepatocytes showed the mostly depressant effects of cytokines on phase I enzymes (table 7).

Thus it would appear that serum from critically ill patients may change drug metabolism by two mechanisms. First, it may contain an enzyme inhibitor. Second, it contains cytokines that may reduce the expression of cytochromes P450.

The Parisian group also showed interferon to have a depressant effect on the expression of cytochromes P450. Viral illness is known to depress drug metabolism [27] and this effect is probably caused by interferon [38, 99, 102]. Interferon may exert its effect in three possible ways. It may cause release of a second mediator, such as IL-1. Alternatively, interferon may induce xanthine oxidase, which increases the amount of free radicals present and may interfere with normal cell function [50]. Finally, interferon may enhance haem turnover, reducing the amount of cytochromes P450 present [38, 100].

TEMPERATURE

Most chemical reactions are sensitive to temperature, going faster as the temperature increases and slower with a decrease in temperature. Despite this, fever does not increase the rate of metabolism of drugs.

Antipyrine (a substance metabolized by at least two cytochromes P450) metabolism was reduced in volunteers who had a fever induced with a pyrogen [39]. Similarly, the metabolism of quinine (also a cytochrome P450 substrate) is decreased during acute malaria and steroid induced fever [149]. This paradoxical finding may be explained by the cause of the fever. Both infections and pyrogens will cause the release of inflammatory mediators. These will reduce the expression and activity of the enzymes responsible for the metabolism of antipyrine and quinine.

Acute hypothermia, induced during cardiopulmonary bypass, has been shown to reduce the clearance of esmolol [72]. These patients were given esmolol by continuous infusion during bypass and when the patient was cooled plasma concentration of esmolol increased, showing a reduction in clearance. Acute hypothermia caused by cardiopulmonary bypass may have more predictable effects on drug metabolism than hyperthermia because it would not be expected to release inflammatory mediators, with their own effects on enzymes. Furthermore, esmolol is metabolized by red cell esterases, rather than cytochromes P450, and these enzymes may be more temperature dependent.

STRESS

Non-traumatic stress has been shown to reduce enzyme function. Pollack and colleagues [120] studied rats exposed to a variety of stresses over 21 days. These included exposure to flashing lights, rocking their cages, food deprivation, isolation and swimming in cold water for 24 h (all, except the last, are remarkably similar to the stresses to which the critically ill are sometimes exposed!). Afterwards they measured the ability of the rats to eliminate antipyrine and hepatic blood flow. Both were decreased.

The reduction in antipyrine clearance cannot be explained merely by the reduction in liver blood flow, since antipyrine is not a high extraction drug and therefore solely dependent on liver blood flow. The increase in circulating catecholamines caused by stress probably decreased liver blood flow. This may, in turn, cause hepatic hypoxia causing a reduction in the enzymes metabolizing antipyrine.

SEX

Male and female rats behave differently when exposed to endotoxin. Each has specific sex-linked enzymes; in the male there is a 35% reduction in CYP 2C11, while in the female only a 17% decrease in CYP 2C12 after endotoxin. The female also shows the initial change and recovers faster than the male [101]. Whether such changes occur in humans is unknown. Little attention has been paid to difference in enzyme expression between men and women, although we have shown a difference in the expression of CYP 3A in liver tissue from organ donors [147].

DIET

Most critically ill patients have an abnormal diet. A change in diet, deficiencies or excesses of a variety of dietary components, is associated with abnormal enzyme function [75, 78, 79, 86, 119, 139, 158, 159] Vitamin C deficiency in guineapigs is associated with a decrease in certain cytochromes P450 [78]. Although scurvy is rare, lack of other vitamins and trace elements, which probably occurs regularly in the critically ill, may result in similar changes.

High fat diets also change cytochrome P450 expression. Parenteral nutrition using large amounts of fat has been shown to increase the oxidation of antipyrine [23]. One potential mechanism for this has been shown in rats fed on a variety of diets, one of which contained excess fat. These rats had an increase in cytochrome P450 2E1, which was associated with an increase in its mRNA. The cause of the increased mRNA was thought to be because the fat stimulated release of growth hormone, in turn changing gene transcription [159].

Starvation and malnutrition cause further changes [86, 139, 159], in particular an increase in cytochrome P450 2E1 [75]. Interestingly, this change may be blocked by the sedative, chlormethiazole [97].

ENDOCRINE DISEASE

Endocrine disease is common in the critically ill, but is poorly recognized. It may be the cause of admission to the intensive care unit; such an example is diabetic ketoacidosis. Also, drugs may also cause it—Addison's disease after etomidate (a potent cytochrome P450 inhibitor) [89, 91] and giving steroids are examples.

Diabetes mellitus is a common disease and for many years changes in the metabolic potential of these patients has been known [12]. However, these changes are only seen in patients with insulin-dependent diabetes and not those patients with type 2 diabetes. The reasons behind this were unclear. Changes in growth hormone and glucagon secretion had been suggested. A French group has shown that insulin itself changes the amount of cytochromes P450 present in isolated hepatocytes by decreasing the half-life of mRNA [34].

Corticosteroids will also change the expression of drug metabolizing enzymes. This may be the endogenous corticosteroid secreted as part of the stress response or exogenous steroid given to treat a disease.

Thyroid disease also changes the response to drugs [44]. Several mechanisms are involved. If patients are hyperthyroid then their heightened mental state will make them resistant to sedatives and analgesic drugs among others. In addition, some test substrates have a reduced half-life because of induced enzymes. Indeed, in some patients the hepatic endoplasmic reticulum has been seen to be hypertrophied on microscopy. Despite these changes there are few reports of changes in drug elimination caused by changes in the drug metabolizing enzymes. However, there are changes in the elimination of drugs in hyperthyroidism caused by changes in the amount and composition of plasma proteins. The most important drug affected by this is warfarin, although others may be similarly affected.

Hypothyroidism produces other changes. There is a 40% reduction in the oxidation of antipyrine, although it is unknown if this also occurs with drugs. Like hyperthyroidism, hypothyroidism changes the elimination of drugs through mechanisms other than changes in enzymes. Renal function is also reduced and this can itself cause an important reduction in the excretion of digoxin and practolol.

Many other hormones are affected by severe illness. Growth hormone is one of these. Its importance in the critically ill is now being recognized. Furthermore, it is a key regulator of the expression of many enzymes [98]. Its secretion is also different between men and women and explains the different expression of the most important drug metabolizing enzymes between the sexes. Other reasons for sex differences in the metabolism of drugs include using the oral contraceptive pill. This leads to a 49% increase in the clearance of paracetamol by inducing both glucuronidation and oxidation [148].

Changes in growth hormone secretion have also been implicated to explain the different effects on drug metabolism caused by morphine, but not by pethidine. Rane and colleagues [66] showed that morphine inhibits its own desmethylation, but not glucuronidation. In a subsequent study [122] they compared rats treated with morphine and pethidine. Morphine suppressed CYP 2C, CYP 3A and CYP 4A and induced CYP 1A2, CYP 2B1 and CYP 2E1. Both the enzyme itself and the mRNA were affected showing that the change occurred at the transcription level. Pethidine caused none of these changes.

The authors also used a variety of control animals exposed to several blocking agents. From this, and the similarity of the changes to other work, they concluded that this was a neuroendocrine effect resulting in a change in growth hormone that then altered the expression of the enzymes. The opioid receptors were not causing them, because pethidine caused no change. It is noteworthy that morphine (but not pethidine) occurs naturally in the brains of mammals [155].

The importance of this work in humans has been investigated. However, drugs such as codeine that depend on metabolism to morphine, may be less effective if morphine is given first.

AGE

The very old and the very young are treated in intensive care units. With both extremes of age significant differences in drug metabolism from the normal population exist. Both metabolism and excretion are affected.

Metabolic activity also varies with age. Phase I enzymes have been shown to change with age in animals [70]. The phase II enzymes responsible for the glucuronidation of morphine also change with age. Morphine is metabolized mostly to morphine-3-glucuronide (M-3G) and morphine-6-glucuronide (M-6G) by two different UDP glucuronyl transferases. In premature infants, Choonara and colleagues [30] showed that the clearance of morphine was decreased compared with children. However, they also noted that the M-3G:morphine ratio in plasma and urine and the M-6G:morphine ratio in urine were higher in children than in neonates. This indicates that there is enhancement of glucuronidation pathways with growth. Since there was no difference in the M-3G:M-6G ratio between children and neonates they also suggested that both glucuronidation pathways develop in a similar fashion.

Table 8 Effects of ageing in humans on various pharmacokinetic variables of drugs metabolized by cytochromes P450 (from [129])

Drug	Age (years)	Plasma half-life ($T_{\frac{1}{2}}$) (h)	Plasma clearance (ml kg^{-1} h)
Aminopyrine	25–30	3	
	65–85	10	
Antipyrine	20–40	12.5	
	65–92	16.8	
Phenobarbitone	20–40	71	
	50–60	77	
	70	107	
Phenytoin	20–43		26
	67–95		42

The elderly (> 65 yr) population is increasing. In the USA in 1980 it made up 11% of the population and is estimated to make up 15% by the year 2040 [60]. Many changes affect the elimination of many drugs in the elderly. These include a decreased body weight, body water, cardiac output, plasma concentration of albumin and an increased body fat. These changes have been well illustrated with midazolam [63]. However, Jacobs and colleagues [73] have also shown a pharmacodynamic sensitivity related to age independent of pharmacokinetic variables. There are significant changes in the elderly in the plasma half-life and clearance of drugs metabolized by cytochromes P450 (table 8).

The exact mechanisms behind these changes in enzymes are unknown. Work in rats has shown significant decreases in the activities of these enzymes with age. In addition, some studies have shown a decrease in rate of induction of these enzymes while others have not [129].

OTHER DRUGS

Many drugs will change the activity of both phase I and phase II systems. This may change the pattern of metabolites made from other drugs by these enzymes. For example M-3G and M-6G are made by different UDP-glucuronyl transferases. Phenobarbitone induces these different enzymes by varying amounts. When the metabolism of morphine was studied in liver microsomes from rats with and without pre-treatment with phenobarbitone the ratio of M-3G:M-6G varied [121]. The glucuronidation of morphine can also be inhibited by a variety of drugs, including oxazepam and salicylamide [112].

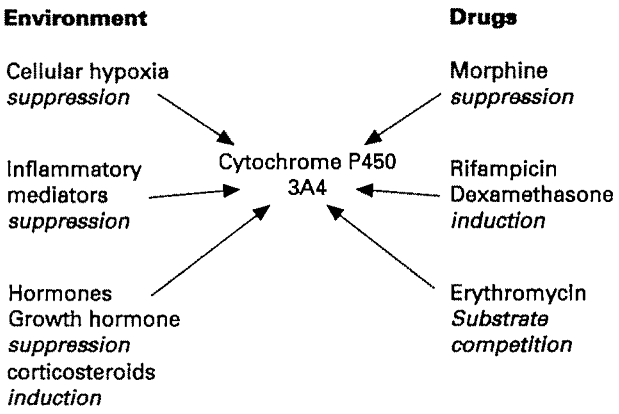

Figure 5 Some of the known factors affecting one enzyme, cytochrome P450 3A, showing how difficult it is to predict its function.

RENAL FAILURE

There is evidence that renal failure is associated with impaired drug metabolism [42] both in an experimental model [44], and in humans [124]. In rats, there is a decrease in hepatic cytochromes P450 after sub-total bilateral nephrectomy of sufficient degree to result in an increase in urea and creatinine [44]. It is also likely that the effect of renal failure on drug metabolism will also vary for different drugs. For example, propranolol, a drug thought to be exclusively cleared by the liver, is eliminated poorly in renal failure [17]. Conversely, the elimination of phenytoin is accelerated in uraemic patients [108].

INTERACTION OF FACTORS

Many factors will simultaneously change enzyme function in the critically ill. Figure 5 illustrates some of the factors that may affect one enzyme. How they interact with each other is unknown.

Metabolites

Morphine is metabolized principally by phase II enzymes to morphine-3 glucuronide (M-3G) and morphine-6 glucuronide (M-6G). Since these are both excreted in the urine, these metabolites will accumulate in renal failure. In 1986 we [133] and others showed that this metabolite accumulates in renal failure causing unexpected and prolonged narcosis in humans [110]. M-6G has been shown to be a potent analgesic and M-3G to antagonize this [56, 140]. It is noteworthy that some patients are unable to make M-6G and obtain poor analgesia from morphine. This suggests that analgesia depends upon the balance of the two metabolites that are produced.

Interestingly, both M-3G and M-6G are highly polar substances and therefore should not cross lipid membranes and so be active. A Swiss group [24] has shown that these two molecules behave as a molecular "chameleon". Both are able to change their configuration according to the environment they are in. When they are in a lipid environment they are fat soluble and in aqueous environment are water soluble.

More recently, one of the glucuronide metabolites of midazolam has also been shown to be active in humans. However, unlike the glucuronides of morphine that are many times more potent than the parent compound midazolam, 1-hydroxy glucuronide has only a tenth of the activity of the parent drug [10]. No molecular modelling has been done with this substance to see it if changes its configuration like morphine.

Other drugs also have active metabolites. These are summarized in table 9.

Extrahepatic sites of drug metabolism

The enzymes that metabolize drugs are found in most cells in the body. It is therefore not surprising that there is extrahepatic metabolism of many drugs [58, 59, 84, 114]. The amount of extrahepatic drug metabolism will vary greatly. In one of our studies with the new opioid, remifentanil, we found normal metabolism during the anhepatic period of liver transplantation [105] while morphine had very little metabolism [20]. This is because the enzymes metabolizing remifentanil are found in blood and other tissues while those metabolizing morphine are concentrated in the liver.

Many organs have been shown both *in vitro* and *in vivo* to metabolize drugs. Not surprisingly, the gut is an active metabolic organ since it is the body's first line of defence when dealing with many xenobiotics, including food! The brush border is the most active. When Kolars and colleagues [84] instilled cyclosporin, through a nasogastric tube, into the small bowel of anhepatic patients they were able to show

Table 9 Important metabolites of sedative and analgesic drugs. (Reproduced from [116])

Parent drug	Metabolite	Comments
Diazepam	Nordesmethyl diazepam, oxazepam	Both of these are active. They have a longer elimination half-life than diazepam. The elimination half-life of nordesmethyl diazepam can increase to 403 h
Midazolam	1-hydroxy midazolam	10 % of the activity of the parent drug
Midazolam	1-hydroxy midazolam glucuronide	Accumulates in renal failure and has $\frac{1}{10}$ the activity of midazolam
Morphine	Morphine-β-glucuronide	Antianalgesic
	Morphine-6-glucuronide	Potent analgesic properties, up to 40 times more active than parent drug when given intracisternly. Longer duration of action than morphine. Will be retained in renal failure
Vecuronium	Nordesacetyl vecuronium	Activity enhanced by hypomagnesaemia
Pethidine	Norphethidine	Can cause fits

significant amounts of metabolites in the portal blood. The gut also contains large amounts of bacteria that also have drug metabolizing enzymes. These bacteria have been shown to metabolize halothane [49].

Several authors [142, 153] have used slices of various organs, not just the intestines, and shown them to play an important part in extrahepatic drug metabolism. For example, many drug metabolizing enzymes are found in the renal cortex [2].

The lung has also been suggested as a site for drug metabolism. Cassidy and Houston [25, 26] have suggested that it may be an important site for phenol metabolism. However, when we studied the metabolism of propofol [59] and remifentanil [36] we could not show any metabolism by the lung.

How important these sites become in critical illness is unknown. There is only one case report of a viraemic patient having a liver transplant and having his extrahepatic sites of drug metabolism assessed by measuring the breakdown of midazolam. In this patient the extrahepatic enzymes appeared to be affected in the same way as enzymes in the liver [114].

The kidneys may also be affected by disease that changes drug metabolism. In patients with unilateral hydro-nephrosis the diseased kidney has less cytochrome P450 activity than the normal side [160]. Other diseases affecting the cortex may have similar effects [54].

Unexpected effects

Although clinicians recognize the effects of the drug on the primary organ unexpected effects can sometimes occur elsewhere in the body. These must be looked for otherwise the effects they cause may be attributed to the underlying disease.

PROPOFOL AND CYTOCHROMES P450

Propofol has achieved popularity as a sedative agent in the critically ill. It is given over many days and this results in a total dose many times larger than is used during anaesthesia being given. Because of this, insignificant effects during anaesthesia may become important in the critically ill. One potential interaction is between propofol and cytochromes P450.

One group in Iowa [8] showed that propofol is a specific inhibitor of rat cytochromes P450. They used microsomes from rats which had been treated with phenobarbitone and isoniazid inducing CYP 2B1, CYP 2C6 and CYP 3A and CYP 2E1. They showed inhibition of CYPs 2B1 and CYP 2C6 but could not show any significant inhibition of CYP 2E1. Another group using microsomes from pig and human liver showed that concentrations of propofol encountered in clinical practice inhibited the oxidative metabolism of sufentanil and alfentanil [74]. We have similarly shown inhibition of midazolam by propofol [unpublished observation].

Mouton-Perry and colleagues [103] have shown that the inhibitory effects of propofol occur in whole animals. They gave dogs propofol and measured the clearance of propranolol. Control animals were give soyabean extract (the solvent for propofol). Propofol caused a 40% decrease in the clearance of propranolol. Several mechanisms for this have been suggested. Interference with some part of the cytochrome P450 responsible for binding the drug has been suggested [8]. More recently, a group from Taipei [28] has shown in microsomes from hamsters, that propofol may bind to the main part of the haem ring in the cytochrome inactivating it. The haem part of the cytochrome is responsible for the addition of oxygen in the same way as haemoglobin. It is noteworthy that in contrast with the work in dogs, they could not reproduce this inhibitory effect in hamsters anaesthetized with propofol and given a variety of probe substrates. The importance of this in humans remains to be elucidated, although it may explain some of the changes seen in a recent study looking at the pharmacokinetics of propofol and alfentanil used together [47].

Deliberate enzyme inhibition

Enzyme inhibition is not always detrimental. The use of the enzyme inhibitor, cilastatin, with the antibiotic imipenem illustrates this. Imipenem is an antibiotic belonging to the carbopenem class of β lactams. It is broken down by the enzyme dehydropeptidase-1, found in brush border microvilli of the proximal tubule. The breakdown of imipenem prevents antibacterial concentrations of imipenem reaching distal parts of the kidney [22]. In urinary tract infections this is a major disadvantage. Dehydropeptidase-1 can be inhibited with cilastatin overcoming this and improving the efficacy of imipenem. Imipenem is marketed as a 1:1 mixture of antibiotic and enzyme inhibitor.

Interestingly cilastatin appears to be not only an enzyme inhibitor it also acts to prevent nephrotoxicity of high dose imipenem in rabbits [18] and cyclosporin in patients after heart transplantation [94]. Various mechanisms have been suggested for this, including changes in blood flow, reduction in tubular uptake of some molecules preventing toxic accumulation or decreasing cellular peptide turnover because of inhibition of the enzyme, but none has been proved [94].

Some volatile anaesthetics, especially halothane, are metabolized to hepatoxic metabolites, usually by CYP 2E1. This enzyme is inhibited by volatile anaesthetic agents and also by disulfiram. In future, inhibition of this enzyme may be used to reduce the toxicity of these drugs [57, 81].

Transport

Once the drug is in the blood it then needs to be transported to the receptor or other site of action and to the organs of elimination. Although there is a lot more information about transport within the blood, little is known about transport from the blood to the enzyme receptor. However, since transport may affect drug metabolism, by altering the amount presented to the enzyme, it is briefly discussed in this review.

There are many proteins in the blood—two are of major importance for carrying drugs. The first,

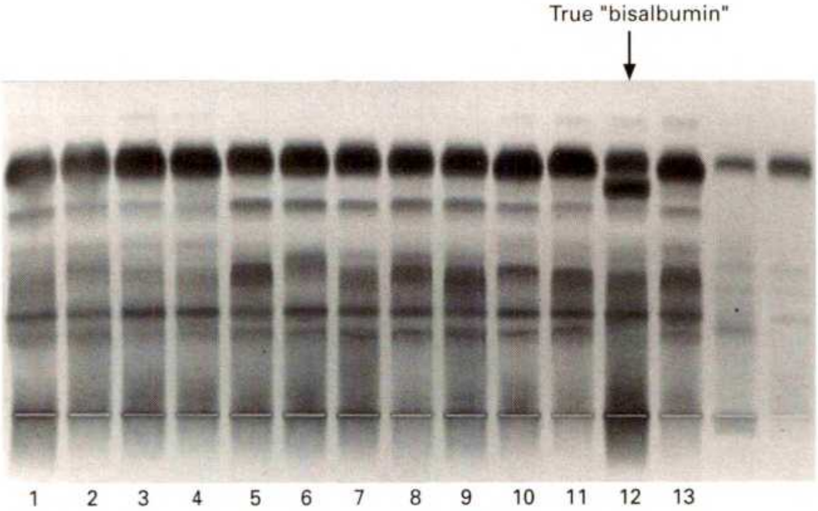

Figure 6 Electrophoretic strip showing true "bisalbumin" in lane 12.

Table 10 Changes in binding of drugs to plasma proteins in patients with renal failure. (From [42])

Drug	Change in binding
Acidic drugs:	
Desmethyldiazepam	Decreased [107]
Phenytoin	Decreased [3, 68, 109]
Benzylpenicillin	Decreased [43]
Salicylate	Decreased [3, 43]
Frusemide	Decreased [4, 123]
Warfarin	Decreased [7, 16]
Basic drugs:	
Disopyramide	Increased [65]
Vancomycin	Decreased [146]
Thiopentone	Decreased [3, 61]
Morphine	Decreased [109]

albumin, carries acidic drugs such as phenytoin and lignocaine. The other, alpha 1 acid glycoprotein, carries basic drugs such as morphine.

Drugs vary in the amount of their protein binding. Some drugs are not highly protein bound whereas others, such as warfarin and diazepam, are highly protein bound. In those drugs with a high protein binding displacement of even a small amount of drug will greatly increase the free or active drug. Thus, with warfarin, which is 99% bound to albumin, displacement of 1% of the boundary drug will double the active amount of drug. However, this increase in free fraction will also result in an increased extraction of the drug by the liver and changes in volume of distribution, reducing this effect [3, 127].

ALBUMIN

Albumin carries many drugs and other endo- and xenobiotics. The importance of albumin for drug transport and many other functions is being questioned. Plasma concentrations of albumin decrease in severe illness and maintaining "normal" plasma concentrations by giving albumin preparations has no effect on outcome [46, 55, 62, 141, 143, 144].

There are probably several reasons for this. Not surprisingly, for a protein with a molecular weight of about 65 000, there are several genetically acquired variants of albumin. These include albumin Reading, Chent, and Makie [95] as well as fast (albumin Naskapi) and slow (albumin Mexico); the last two

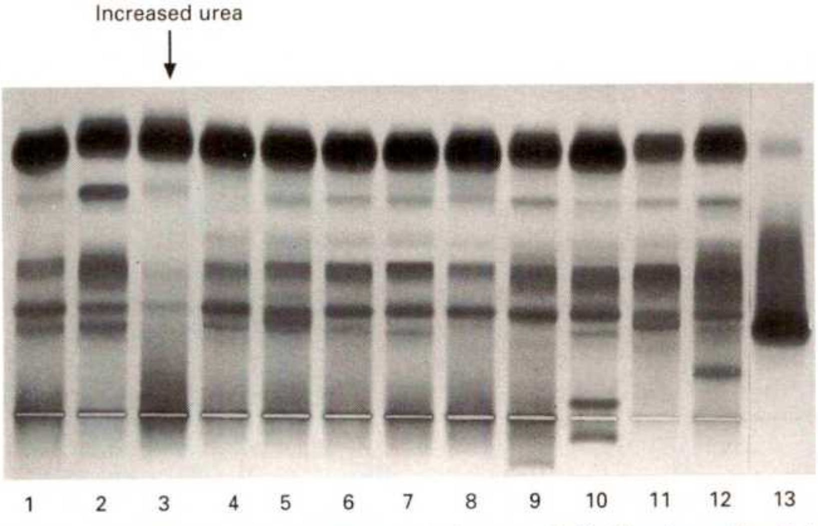

Figure 7 Electrophoresis of albumin. Lane 3 shows albumin from a critically ill patient with a high plasma concentration of urea. The front edge is "faster" than adjacent lanes.

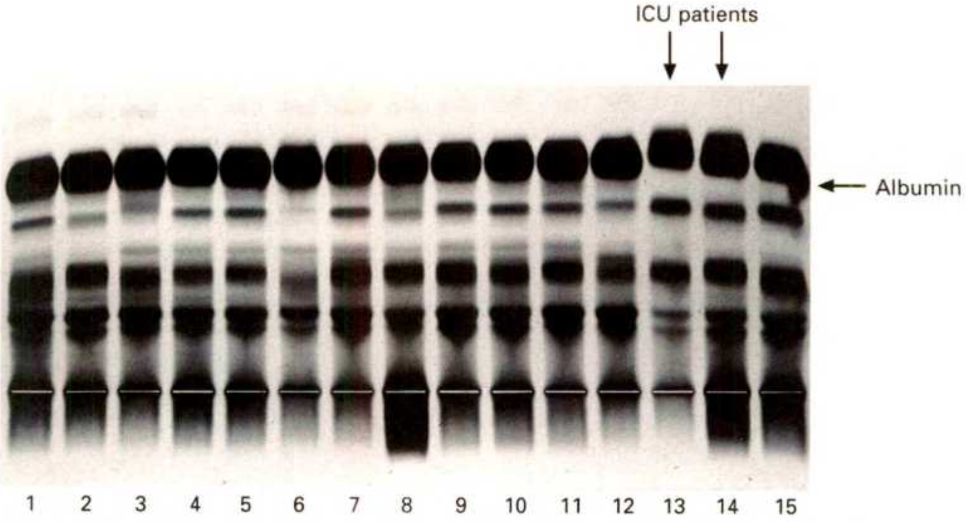

Figure 8 Electrophoresis of albumin from critically ill patients (lanes 13 and 14), other patients and control (lane 15). The albumin from the critically ill patients migrates faster than the others.

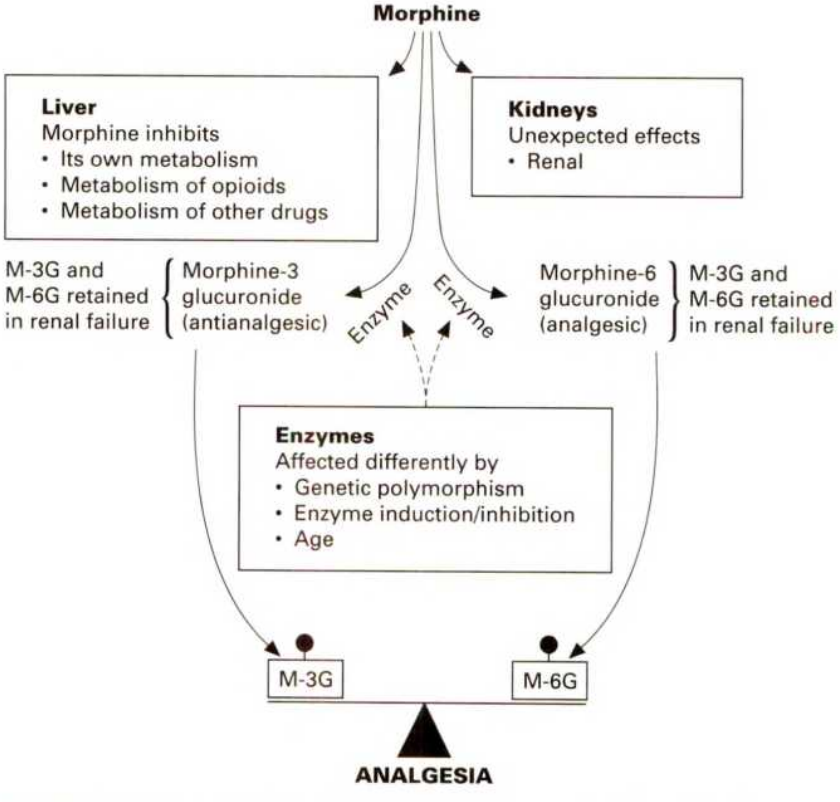

Morphine
Liver
Morphine inhibits
• Its own metabolism
• Metabolism of opioids
• Metabolism of other drugs
Kidneys

Figure 9 How understanding the metabolism of morphine explains *some* of its unpredictability.

refer to electrophoretic mobility. An example of this is shown in figure 6. Lane 12 has a "double head" to it showing it to be hereditary, bisalbuminaemia.

Furthermore, the configuration of albumin also changes during illness. For example, in renal failure the binding of drugs to proteins may be increased or decreased (table 10).

The mechanism for the change in the configuration of albumin has been described for pancreatitis. Kobayashi and colleagues [83] have shown that pancreatic enzymes may cause bisalbumin to appear. Similarly, high dose antibiotics, urea or bilirubin may also cause this [83, 90]. The effects of urea on the electrophoretic pattern of albumin are shown in figure 7.

We have recently confirmed that this change in the electrophoretic characteristic occurs in the critically ill. Figure 8 shows a control lane (15) and next to it albumin from two critically ill patients. The remainder of the figure consists of outpatients and inpatients from the general wards. The two critically ill patients have albumin that electrophoreses more quickly than the others. Both the cause of the change and its significance are unknown, but it does show that albumin is not an inert molecule and changes with disease.

More recently, there is increasing awareness that the configuration of albumin found in pharmaceutical preparations is different from the configuration of albumin in the blood. Finally, there are some normal humans who do not make albumin at all, although studies on drug transport mechanisms have not been carried out. However, in analbuminaemic rats thyroxine (normally bound to albumin) transport is normal. [95]

The changes in albumin configuration in disease give strength to the belief of some that protein binding of drugs is not of such great importance as was previously thought, although others would contest this [126]. As albumin is expensive this is an area that is clearly in need of urgent investigation since one of the few arguments for supporting plasma albumin concentrations in the critically ill is to return drug carriage to normal. Infusing exogenous albumin may not achieve this.

ALPHA$_1$ ACID GLYCOPROTEIN

This protein increases after stress of many types, including surgery. It binds many drugs such as bupivacaine and so might be expected to reduce the free fraction of them [19]. However, this has not been shown and there are several reasons for this. Several different forms exist [130, 131] and these change with the severity and type of disease [93]. This may be related in some way to the inflammatory response [151]. Other changes also include an increase with age [157].

Application of our knowledge about drug metabolism

Understanding isolated changes in enzyme function unfortunately will not allow early prediction, at the moment, of how it will function in the critically ill. Some of the changes affecting one enzyme only are shown in figure 9. However, understanding these changes does mean that the unpredictability of drug metabolism becomes predictable—clinicians know what to look out for.

Acknowledgements

I thank Patrick Maurel, Mike Tarbit and Martin Bayliss for their encouragement and support; Also Dr J. Calvin for figures 8, 9 and 10. I also thank Rita Pickering and Pascale Diesel for their help with the manuscript.

Determinants of splanchnic blood flow

J. TAKALA

The splanchnic region participates in the regulation of circulating blood volume and systemic blood pressure [60]. Major reduction of splanchnic blood volume and flow can be vital in defending the perfusion of the brain and the heart in acute hypovolaemia, but prolonged hypoperfusion of the splanchnic region will inevitably lead to hypoxic tissue injury [55]. The splanchnic region is also an important source and target of inflammatory mediators, which have a major impact on both systemic and regional blood flow and tissue functions [45]. The splanchnic circulation is in close interaction with the systemic haemodynamics under normal conditions. In the intensive care patient at risk of multiple organ failure, there is a complex and poorly understood interaction between the splanchnic blood flow, metabolic demands of the tissues and the mediators of inflammation and vasoregulation.

Inadequate splanchnic blood flow and tissue perfusion are likely to contribute to the development of organ failures and increased mortality in various categories of intensive care patients [8]. Monitoring of gastric intramucosal pH (pH_i) or intramucosal $P\text{CO}_2$ by gastrointestinal tonometry has provided an indicator of splanchnic tissue perfusion that is feasible for clinical use in intensive care [15, 18, 19, 27, 30, 32, 47, 48, 49]. Clinical studies using gastrointestinal tonometry have produced evidence to support the concept of a link between inadequate splanchnic tissue perfusion and multiple organ failure.

Gastric intramucosal acidosis, suggesting inadequate splanchnic tissue perfusion, is relatively common: up to 50% of patients admitted to intensive care with signs of circulatory failure, 50% of patients undergoing elective cardiac surgery and 18% of patients undergoing abdominal aortic surgery have at least transient episodes of gastric intramucosal acidosis [15, 18, 19, 30, 32, 47, 48, 49]. Patients with gastric intramucosal acidosis on admission to intensive care have an increased occurrence of multiple organ failure and increased mortality [30, 32, 47, 48]. Prevention and treatment of gastric intramucosal acidosis by administration of fluids and vasoactive drugs improves the outcome of those patients with normal pH_i on admission [32, 49].

The mechanisms responsible for the increased morbidity and mortality related to the inadequate splanchnic perfusion are far from being solved. Evidently alterations in systemic haemodynamics can impair the splanchnic blood flow and tissue perfusion [33, 55]. Tissue hypoxia with consequent direct hypoxic tissue injury, although likely to contribute, is clearly a too simplistic explanation. Translocation of bacteria and toxic substances, as a result of hypoxic intestinal mucosal injury, may occur but is unlikely to be a major factor [14]. Inadequate mucosal perfusion increases the intestinal mucosal permeability [20]. All these mechanisms and ischaemia and reperfusion of splanchnic tissues may contribute to the activation of inflammatory mediator networks, and thereby further modify the circulatory and metabolic responses locally, within the splanchnic region and in extrasplanchnic organs [46].

This review discusses the physiology of splanchnic blood flow, obtained largely from experimental studies, and the relatively limited available human data on splanchnic blood flow in patients at risk of multiple organ failure.

Splanchnic blood flow in normal conditions

The arterial inflow to the splanchnic region is via the coeliac trunk and the superior and inferior mesenteric arteries [17] (table 1). The venous efflux via the portal vein represents the sum of all splanchnic arterial influx, except the hepatic arterial flow. The venous efflux via the hepatic veins (i.e. the blood flow through the liver) represents the total hepatosplanchnic blood flow; in principle, the hepatic arterial flow could be estimated as the difference between portal venous flow and total hepatic venous efflux.

Hepatic arterial and portal venous blood flow interact closely. Owing to this "hydrodynamic" interaction, an alteration of flow to one of the circuits leads to an opposite change in the other circuit. The interaction tends to maintain total liver blood flow constant [57].

The blood flow of the small intestinal villus deserves special consideration. The artery and vein of the villus run in parallel but their blood flows are

(*Br. J. Anaesth.* 1996; **77**: 50–58)

Key words

Blood, flow. Arteries. Oxygen, uptake. Gastrointestinal tract, blood flow.

JUKKA TAKALA, MD, PHD, Critical Care Research Program, Department of Intensive Care, Kuopio University Hospital, PO Box 1777, FIN-70211, Kuopio, Finland.

Table 1 Arterial blood supply to the splanchnic region (general overview, anatomical variation is common)

Main artery	Main tributary arteries	Main areas supplied
Coeliac trunk	Common hepatic (branches: right gastric and gastroduodenal)	Liver; parts of stomach, duodenum and pancreas
	Splenic	Spleen; parts of stomach and pancreas
	Left gastric	Parts of stomach and lower oesophagus
Superior mesenteric artery	Inferior pancreaticoduodenal, intestinal (12–15 branches), ileocolic, right colic, middle colic	Small intestine, caecum, ascending colon, most of transverse colon; parts of duodenum and pancreas
Inferior mesenteric artery	Left colic, sigmoid, superior rectal	Descending and sigmoid colon; parts of transverse colon and rectum

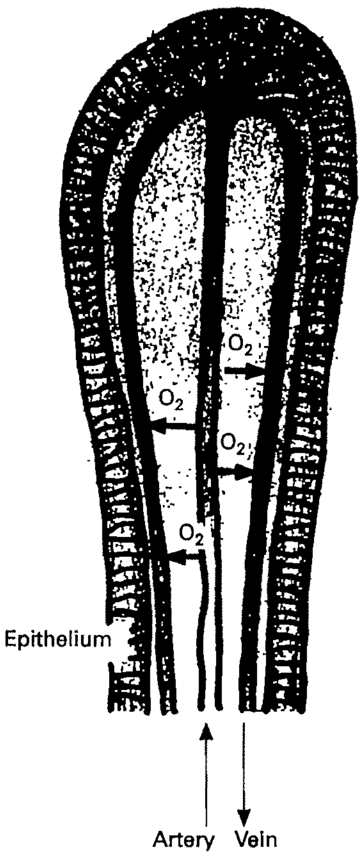

Figure 1 Schematic presentation of the intestinal villus countercurrent exchange of oxygen. Oxygen diffuses from the artery to the villous veins throughout their course to the tip of the villus. This results in a descending gradient of Po_2 from the base of the villus to the tip.

in opposite directions (fig. 1). The artery forms a dense capillary network close to the top of the villus. This anatomical arrangement allows countercurrent exchange of oxygen from the artery to the vein along their course within the villus [42]. This results in a descending gradient of tissue Po_2 from the base of the villus to its tip. This gradient is inversely related to the blood flow. An alternative explanation for the tissue Po_2 gradient in the villus may be a higher metabolic activity of the absorptive cells at the tip [42]. Regardless of the mechanism, the lower Po_2 at the tip may make the villus susceptible to tissue hypoxia, if vasoconstriction occurs for any reason.

Table 2 Splanchnic and whole body blood flow and oxygen uptake at rest [6, 24, 57, 77]

	Splanchnic	Whole body	Splanchnic contribution to total (%)
Blood flow (litre min^{-1} m^{-2})	0.50–0.80	2.5–4.0	20–30
Oxygen consumption (ml min^{-1} m^{2})	20–40	110–150	20–35
Oxygen extraction fraction	0.22–0.35	0.22–0.30	

MEASUREMENT OF SPLANCHNIC BLOOD FLOW

Human studies on splanchnic blood flow are relatively scarce owing to methodological difficulties of quantitative measurements. Direct measurement of splanchnic blood flow is practically impossible without surgery for anatomical reasons (table 1; multivessel influx and efflux, mixing of portal venous and hepatic arterial blood within the liver). The same is true for intravascular pressures within the splanchnic bed. Accordingly, much of the basic splanchnic circulatory physiology has been extrapolated from experimental studies and has not been confirmed in normal humans.

Total hepatosplanchnic blood flow can be estimated according to the Fick principle from the hepatic uptake of substances that are exclusive metabolized by the liver and distributed in the plasma [9, 36, 71]. Hepatic venous catheterization is necessary for the measurement. A detailed description of this technique and its evaluation both in normal subjects and in intensive care patients has been published [71].

SPLANCHNIC BLOOD FLOW AND OXYGEN UPTAKE

The splanchnic blood flow should be considered in relation to the splanchnic metabolic activity and the oxygen extraction capabilities of the splanchnic tissues. Normally, the total hepatosplanchnic blood flow is approximately 20–30 % of cardiac output. Roughly 80 % of the total hepatic blood flow reaches the liver via the portal vein and 20 % via the hepatic artery (a tributary of the coeliac trunk). The splanchnic oxygen consumption at rest is approximately 20–35 % of whole body oxygen consumption.

This results in a slightly increased oxygen extraction fraction, compared with the systemic oxygen extraction at rest [6, 24, 57, 77] (table 2).

When the metabolic demands of the splanchnic region increase, for example, as the result of feeding, blood flow to the relevant organs increases in proportion to the increase in regional oxygen consumption. Accordingly, the splanchnic oxygen extraction ratio is well maintained. If the oxygen extraction is very low, increased extraction may precede increases in blood flow. The appropriate increase in splanchnic perfusion can be obtained by either increased cardiac output or its redistribution, or by the combination of the two mechanisms [5, 23, 57, 67].

Probably because of its important role in the regulation of blood volume and redistribution of blood flow, the splanchnic region has a large capacity to adapt to reduced blood flow by increasing the oxygen extraction. During exercise, blood flow is redistributed from the splanchnic region to the working muscle [58, 59]. Splanchnic oxygen extraction increases consequently. At least in the short term, the normal metabolic processes are maintained at high levels of oxygen extraction. In extreme conditions, when hypoxia due to reduced inspired oxygen fraction is superimposed on exercise, splanchnic oxygen extraction may increase to close to 90%. During this acute experiment, hepatic extraction of indocyanine green decreased, suggesting that the liver function was deteriorating [58].

The available data in humans suggest that the liver is well protected against hypoxia in normal subjects, at least when the exposure is short. On the other hand, the gut may be more susceptible to develop local or regional hypoxia. Experimental studies suggest that the gut may become hypoxic already, when its oxygen extraction approaches 70% [50, 78].

CONTROL OF SPLANCHNIC BLOOD FLOW

Gut blood flow

Gut blood flow is regulated by intrinsic and extrinsic mechanisms. The intrinsic factors include local metabolic control and myogenic control, local reflexes and locally produced vasoactive substances. The extrinsic factors include sympathetic innervation, circulating vasoactive substances and systemic haemodynamic changes [23]. The total blood flow to the gut wall is unevenly distributed in the four main layers—the mucosa, the submucosa, the muscularis and the serosa. The mucosa and the submucosa receive most of the flow, up to 90%. Changes in the total gut blood flow may influence the flow to the different layers to varying extent.

The local metabolic control responds by local vasodilatation, if blood flow is insufficient for the local metabolic needs [23, 25]. The actual signal for the vasodilatation is not known. Both tissue Po_2 and products of cell metabolism have been proposed. The myogenic control responds to an increase in vascular transmural pressure by arteriolar vasoconstriction [23, 35]. These two control mechanisms interact to maintain blood flow adequate for metabolic needs, and to minimize changes in the intestinal capillary pressure and transcapillary fluid flux. Nitric oxide participates the vasoregulation of the hepato-splanchnic bed; its role is discussed separately later.

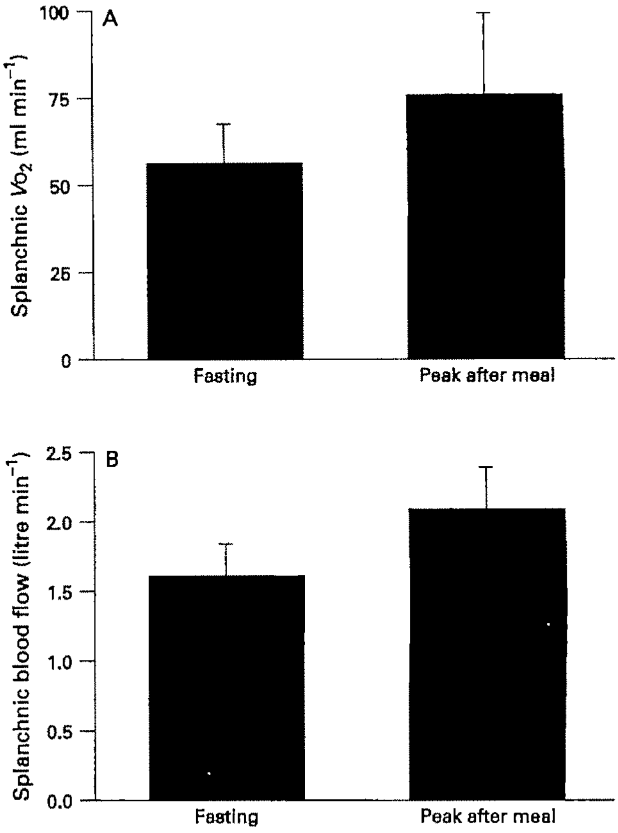

Figure 2 Effect of feeding on splanchnic blood flow and oxygen consumption in healthy subjects [data adapted from ref. 34]. A: Peak splanchnic oxygen consumption following a standard meal (mean (SD)). B: Peak splanchnic blood flow following a standard meal (mean (SD)).

Intestinal blood pressure–flow autoregulation is much weaker than the autoregulation of, for example, renal blood flow [23]. When arterial pressure decreases, blood flow decreases despite a vasodilatory response. The autoregulation is enhanced by feeding: the blood flow is better maintained in response to a decrease in perfusion pressure in the fed state (i.e. with intraluminal food present) than in the starved condition.

The response of the intestinal vasculature to an increase in venous outflow pressure depends on the adequacy of perfusion [23, 68]. If perfusion is sufficient for metabolic needs, an increase in the venous pressure results in arteriolar vasoconstriction (myogenic control). If perfusion is poor and venous pressure increases, the vascular resistance decreases and the capillary density increases (metabolic control).

The gut blood flow has a distinct response to feeding [23]. Digestion results in pronounced postprandial hyperaemia (fig. 2). Several mechanisms are probably involved: a local reflex to the presence of luminal contents, the release of vasoactive gastrointestinal hormones (e.g. gastrin, secretin, cholecystokinin) and the increase in gut metabolism (metabolic control) [23, 34].

The extrinsic neural control of gut blood flow is limited primarily to the sympathetic nervous system.

Sympathetic nervous activity reduces gut blood flow by increasing the vascular resistance of the arteries and arterioles; the veins have more limited sympathetic innervation. During persisting stimulation, the blood flow starts to recover after initial reduction ("autoregulatory escape") [23, 65]. After the stimulation, blood flow increases transiently to a higher level than before the stimulation [23].

Catecholamines are the most important circulating endogenous vasoactive substances that influence the gut blood flow. Alpha-adrenoceptor stimulation results in vasoconstriction and beta-adrenoceptor stimulation in vasodilatation. Accordingly, noradrenaline with predominantly alpha-adrenoceptor activity can be expected to increase the intestinal vascular resistance, whereas the effects of adrenaline are dose-dependent: vasodilatation at low doses and vasoconstriction at increasing doses when alpha-stimulation predominates. The net effects of circulating catecholamines on gut blood flow depend on the concomitant effects on cardiac output [3, 23]. Vasopressin and angiotensin are both potent intestinal vasoconstrictors. Their physiological role in the control of gut blood flow is not certain. They may both be involved in the intestinal vasoconstriction in acute hypovolaemia, and also modulate the response to sympathetic nerve stimulation and noradrenaline [16, 23].

Hepatic blood flow

There are three principal determinants of hepatic blood flow. The vascular resistance across the intestine determines the mesenteric influx and thereby the portal venous flow. The hepatic arterial resistance determines the hepatic arterial flow. The intrahepatic portal venous resistance is less important, since the portal venous flow is mainly determined by the outflow from the intestine, that is the resistance across the intestine. Finally, the hydrodynamic interaction between the hepatic arterial and portal venous flow, as described before, tends to compensate for any change in one of the inflows to the liver by a reciprocal change in the other [6, 57]. The hydrodynamic interaction, also called the hepatic arterial buffer response, is regulated by adenosine [39].

Autoregulation has little importance in the regulation of hepatic arterial pressure-volume relationship; the relationship between the arterial pressure and the flow is approximately linear. The hepatic portal venous bed clearly lacks autoregulation and has a linear pressure–flow relationship [6, 57].

Sympathetic nervous activity is the principal neural mechanism that influences hepatic blood flow. Sympathetic nerve stimulation evokes an increase in the hepatic arterial and portal resistance. The arterial vasoconstriction is transient and has similar autoregulatory escape as the intestinal vasoconstriction. In contrast, the portal response has a slower onset, but the increase in resistance is sustained, once established [26, 57]. In addition to the changes in vascular resistances, sympathetic nerve stimulation also reduces the hepatic volume, probably via contraction of the hepatic capacitance vessels. The volume reduction has a slow onset, persists throughout the stimulation and recovers more slowly than it develops [7, 57].

Role of nitric oxide in splanchnic blood flow regulation

Recent experimental studies have demonstrated that nitric oxide is important in the maintenance of basal vasodilatation in the mesenteric vasculature and the hepatic artery [2, 44]. In an anaesthetized pig model, inhibition of nitric oxide synthesis (non-selective inhibition of both constitutive and inducible nitric oxide synthase) increased hepatic arterial resistance but had no effect on the portal vascular resistance, while the hepatic arterial autoregulation was enhanced. The hydrodynamic interaction between the hepatic arterial and portal vein blood flow (hepatic arterial buffer response) was present after nitric oxide inhibition. After administration of endotoxin, both the hepatic arterial buffer response and autoregulation were abolished, independent of nitric oxide. Inhibition of nitric oxide synthesis after endotoxin increased the resistance of both hepatic artery and portal vein [2]. This suggests that during experimental endotoxin shock, nitric oxide is important in preserving the blood flow across the splanchnic bed. While these observations cannot be directly extrapolated to human septic shock, they do suggest that non-selective nitric oxide inhibition in septic shock may improve blood pressure at the expense of splanchnic perfusion.

Splanchnic blood flow in patients at risk of multiple organ failure

Only very few studies with quantitative measurements of splanchnic blood flow in intensive care patients have been published [1, 10, 11, 22, 28, 29, 52–54, 62, 63, 69, 71–73, 76]. The results have clearly demonstrated that data obtained from experimental studies or more stable patients should be extrapolated to the intensive care patient with great caution. The determinants, clinical relevance and the time course of splanchnic blood flow abnormalities in patients at risk of multiple organ failure have not been well established.

All quantitative splanchnic blood flow studies in intensive care patients at risk of multiple organ failure deal with the total hepatosplanchnic blood flow as measured by the Fick principle [1, 10, 11, 22, 28, 29, 52–54, 62, 63, 69, 71–73, 76]. Gastrointestinal tonometry cannot be used as a surrogate measure of hepatosplanchnic blood flow, since there is no consistent relationship between splanchnic blood flow and measurements obtained by gastric tonometry [53, 54, 72, 73]. Hence, pH_i will be only discussed briefly in the context of response to therapy aimed at improving splanchnic perfusion.

The pathophysiology of splanchnic blood flow and inadequate splanchnic tissue perfusion in intensive care patients is multifactorial. Two substantially different patterns of changes in splanchnic blood flow and metabolic demand are common in intensive care patients: one observed in low flow states [38, 53,

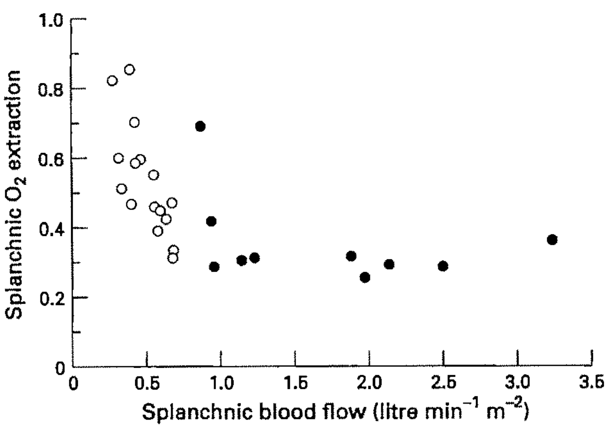

Figure 3 Splanchnic blood flow and oxygen extraction after cardiac surgery and in patients with septic shock and vasopressor therapy [data adapted from refs 62 and 63]. (○) After cardiac surgery; (●) septic shock + vasopressors.

54, 63, 64, 72, 73] and another in severe inflammatory conditions, infections and septic shock [1, 10, 11, 22, 28, 29, 62, 69, 76].

SPLANCHNIC BLOOD FLOW IN LOW FLOW STATES

In low flow states (e.g. cardiogenic shock) and hypovolaemia (without major injury or sepsis), splanchnic blood flow decreases without major changes in splanchnic metabolic demand [53, 54, 63, 72, 73]. In these conditions, perfusion of the heart and the central nervous system is maintained at the expense of the peripheral tissues and the splanchnic region. Once splanchnic vasoconstriction develops in response to hypovolaemia, the recovery of the blood flow will be prolonged: the increased splanchnic vascular resistance and reduced blood flow persists after the circulating blood volume has been restored and systemic haemodynamics have been stabilized [16]. This may increase the risk of inadequate splanchnic perfusion both after resuscitation of hypovolaemia and in intensive care patients susceptible to acute blood volume changes (e.g. as a result of capillary leak) [70].

In low flow states, vasoregulation is usually well preserved and an increased oxygen extraction compensates for the reduction of blood flow (fig. 3). Fully developed physiological compensation may preserve adequate splanchnic tissue oxygenation even during markedly reduced hepatosplanchnic blood flow. The limits of compensation and the time of tolerance for splanchnic hypoperfusion have not been well defined. Perioperative hepatic vein oxygen saturation below 30% during liver resection was associated with postoperative liver dysfunction [37], whereas brief exposure to lower hepatic venous saturation (or increased splanchnic oxygen extraction) have been reported during and after cardiac surgery without any major consequences [38, 53, 63, 64]. The splanchnic blood is defended at the expense of peripheral blood flow in low cardiac output syndrome after cardiac surgery [53, 63].

Nevertheless, prolonged hypovolaemia or low cardiac output will inevitably lead to splanchnic tissue hypoxia and increase the risk of multiple organ failure. It is reasonable to assume that a slowly developing low splanchnic blood flow is better tolerated than an acute reduction.

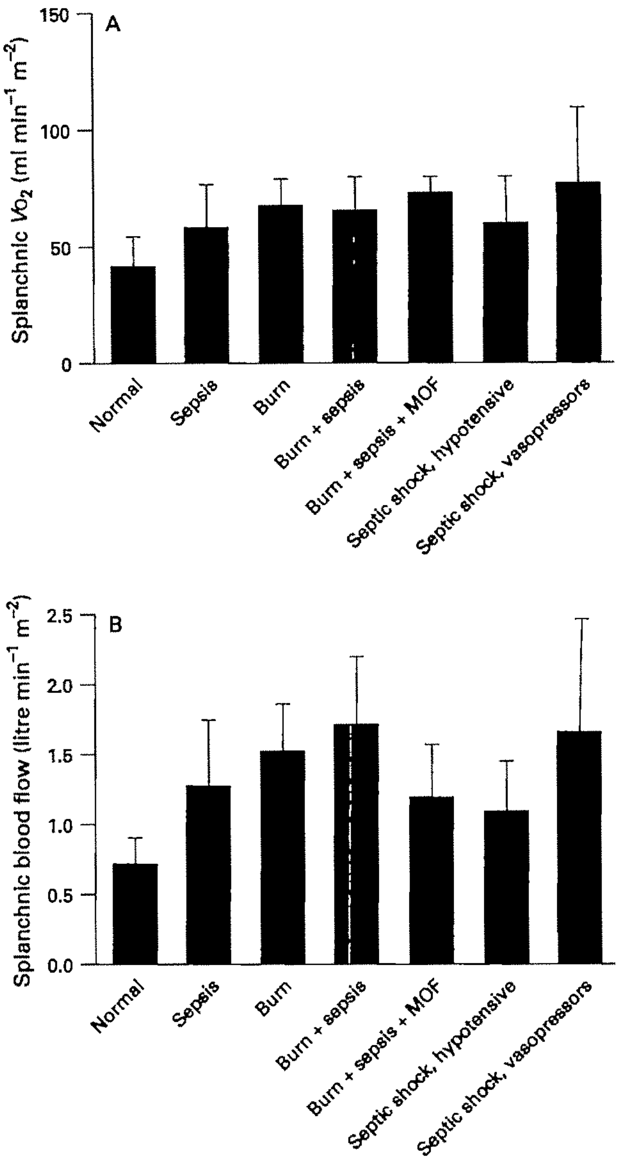

Figure 4 Increased splanchnic oxygen demand and blood flow in sepsis. A: Splanchnic hypermetabolism tends to increase with increasing severity of sepsis [data adapted from refs 11, 62 and 76]. B: Splanchnic blood flow and the severity of sepsis [data adapted from refs 11, 62 and 76].

SPLANCHNIC BLOOD FLOW IN INFLAMMATION AND INFECTION

In severe inflammation (e.g. systemic inflammatory response syndrome or SIRS, septic infections, septic shock), the metabolic demand for oxygen in the splanchnic region is increased [1, 10, 11, 22, 28, 29, 62, 69, 76]. In patients with normal or hyperdynamic haemodynamics, the total splanchnic blood flow is also higher than normal, but the increase in oxygen consumption is disproportionate to the increase in blood flow, and necessitates high oxygen extraction (figs 3 and 4). This appears to be the case regardless of whether stable haemodynamics have been obtained by fluids alone or with the aid of vasoactive

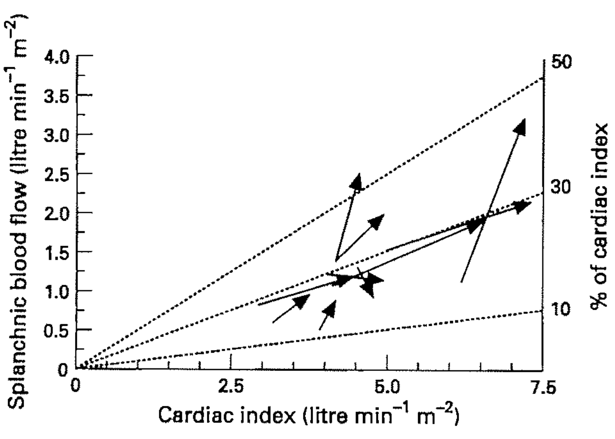

Figure 5 Changes in splanchnic blood flow in septic shock in response to treatment of hypotension with vasopressors [data adapted from ref. 62]. Wide interindividual variability is characteristic of the response.

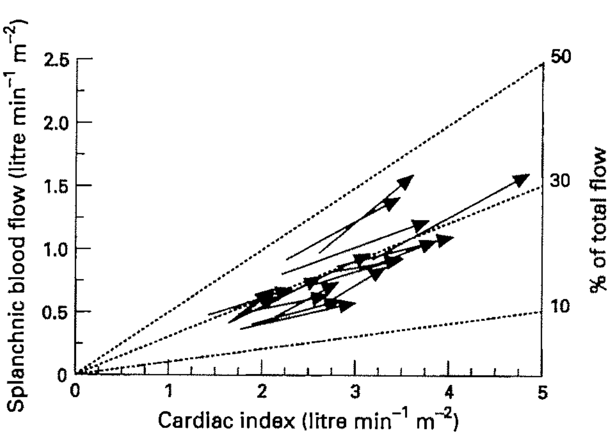

Figure 6 Changes in splanchnic blood flow in response to dobutamine after cardiac surgery [data adapted from ref. 53]. Splanchnic blood flow changes parallel the changes in cardiac output.

drugs [1, 10, 11, 22, 28, 29, 62, 69, 76]. In hyperdynamic septic shock during hypotension, splanchnic blood flow and splanchnic oxygen consumption are higher than normal and the splanchnic oxygen extraction is high [62]. Correction of hypotension by vasopressor drugs tends to increase the splanchnic blood flow further in hyperdynamic septic shock, although individual responses may vary (fig. 5) [62].

Endothelial injury is common in sepsis and contributes to abnormal vascular tone, blood flow maldistribution and development of hypovolaemia [8, 14, 46]. In addition, severe sepsis is almost invariably accompanied by acute respiratory failure, which limits the systemic oxygen delivery. Myocardial depression is also common in sepsis and many limit the response of systemic blood flow to the increased oxygen demand [51]. Under these circumstances, the splanchnic hypermetabolism increases the risk of splanchnic oxygen delivery/demand mismatch, and even subtle changes in blood volume, cardiac output, arterial oxygenation or oxygen demand in other tissues may lead to an imbalance between splanchnic oxygen delivery and demand.

THERAPEUTIC INTERVENTIONS AND SPLANCHNIC BLOOD FLOW

Volume resuscitation

The blood volume can be expected to have a major impact on splanchnic blood flow [13, 16, 55]. Indeed, reduction of splanchnic blood flow has been demonstrated in normal subjects after controlled small-volume haemorrhage [12, 56], and after simulated hypovolaemia following the application of lower body negative pressure [16]. Restoration of blood volume after simulated hypovolaemia was associated with a protracted reduction of splanchnic blood flow. Effects of blood volume on splanchnic blood flow in intensive care patients have not been published. Indirect data from studies using volume resuscitation to improve gastric pH_i suggests that restoration of blood volume is of primary importance in assuring adequate splanchnic perfusion in intensive care patients [32, 47–49].

Adrenergic agents

Vasoactive drugs, especially sympathomimetic amines are used frequently to support tissue perfusion in circulatory failure. The effects of sympathomimetic drugs on splanchnic blood flow in intensive care patients can not be predicted from their pharmacological characteristics alone or extrapolated from experimental models. Traditionally, the potential effects of adrenergic agents on regional perfusion have been interpreted in terms of their relative adrenergic receptor activity. In critically ill patients, the effects may be modified, for example as the result of receptor downregulation. In experimental studies, alpha-adrenergic stimulation by dopamine, noradrenaline and adrenaline increase renal and visceral vascular resistance and reduce renal and visceral blood flow [61]. The effects of dobutamine depend on the balance between its alpha-mediated vasoconstriction and beta-mediated vasodilatation [74]. Dopexamine with $beta_2$- and dopaminergic properties and without alpha-stimulation may have beneficial effects on splanchnic blood flow [41].

In 10 patients with septic shock, correction of hypotension by administration of vasopressor doses of dopamine increased splanchnic blood flow, whereas the effects of noradrenaline were more variable [62]. On the other hand, dopamine worsened gastric mucosal acidosis in septic shock, while noradrenaline resulted in increased gastric mucosal pH despite identical effects on systemic haemodynamics [43].

In patients with chronic congestive heart failure, dopexamine increased the splanchnic blood flow whereas neither dopamine nor dobutamine had an effect [40]. In contrast, both dobutamine and dopexamine consistently increased splanchnic blood flow immediately after cardiac surgery (figs 6 and 7) [53, 63, 72]. Despite the major increases in total splanchnic blood flow, both dobutamine and dopexamine lowered the gastric pH_i or failed to correct the gastric mucosal acidosis [53, 72]. These effects were even more prominent in patients with low cardiac output [53]. On the other hand, dobutamine corrected gastric mucosal acidosis in patients with

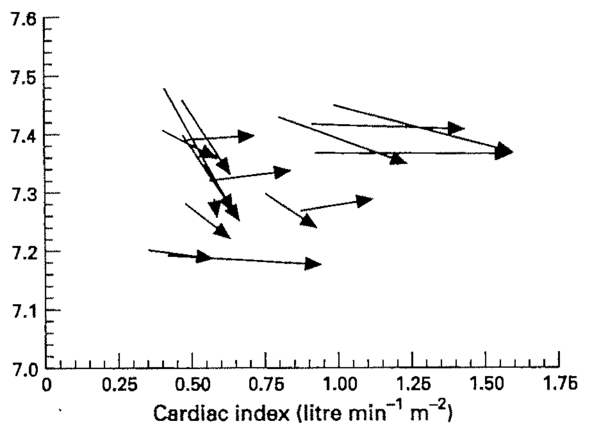

Figure 7 Changes in splanchnic blood flow and gastric pH_i in response to dobutamine after cardiac surgery [data adapted from ref. 53]. Gastric mucosal acidosis worsens especially in patients with low cardiac output despite the increased splanchnic blood flow.

sepsis [31]. Evidently, the underlying disease can modify the splanchnic blood flow responses to vasoactive drugs.

The cause for the decrease in gastric pH_i despite increased blood flow is not clear. The effects of a vasoactive drug may not be uniform throughout the splanchnic region: vasopressor therapy with dopamine or noradrenaline in experimental endotoxin shock increases regional vascular resistance of the colon, while the perfusion in the other parts of splanchnic region is well maintained [4]. The effects of vasoactive drugs on microcirculation may differ despite similar effects on blood flow distribution in major vessels [21]. Observations in experimental peritonitis support this concept: treatment with dobutamine produced more hepatocellular damage compared with dopexamine [75]. The catecholamines may also markedly modify the activity of various metabolic pathways in the liver [3] and simultaneously alter the splanchnic blood flow and its distribution. Accordingly, catecholamines may induce regional perfusion abnormalities and alter the balance between regional oxygen delivery and tissue metabolic demands.

Non-adrenergic vasodilators

The effects of vasodilators on splanchnic blood flow are controversial. Experimental studies suggest that vasodilators (adenosine and isoprenaline) may induce a vascular steal phenomenon within the intestinal circulation by redistributing the blood flow despite an overall increase [66].

In patients with chronic congestive heart failure, nitrates and sodium nitroprusside had no effect on the hepatosplanchnic blood flow despite increased cardiac output, indicating blood flow redistribution [40]. In contrast, sodium nitroprusside increased hepatosplanchnic blood flow in parallel with cardiac output in postoperative cardiac surgery patients [54]. Despite the increase in splanchnic blood flow, gastric pH_i decreased slightly.

Angiotensin converting enzyme inhibitors either had no effect or slightly reduced the hepatosplanchnic flow in cardiac failure [40]. After cardiac surgery, enalapril had no effect on either cardiac output or hepatosplanchnic blood flow, but reduced the gastric pH_i [52].

The effect of vasodilators on hepatosplanchnic blood flow or gastric pH_i have not been studied in septic patients. Nevertheless, the available data suggest that also the effects of vasodilators are modified markedly by the underlying clinical condition. It seems likely that redistribution of blood flow may occur at the level of both macro- and microcirculation.

Splanchnic ischaemia/reperfusion and multiple organ failure

W. L. Biffl and E. E. Moore

Multiple organ failure (MOF) remains the leading cause of delayed mortality in surgical intensive care units. A recent epidemiological review revealed that 61% of late deaths in our trauma centre were the result of organ failure [117]. Once established, MOF defies our standard critical care supportive measures: mortality ranges from 40–100%, and is related directly to the number and duration of organ failures [65]. Unfortunately, basic laboratory investigations have been hampered by a lack of understanding of its underlying pathophysiology. As a result, neither the incidence nor the mortality of the syndrome has improved significantly in recent years. Our trauma research centre has actively sought to define and characterize MOF, and to elucidate the mechanisms responsible for its progression. This review will attempt to highlight our current knowledge, particularly with regard to the role of splanchnic ischaemia and reperfusion (I/R) in MOF. It is our hope that by identifying pathogenetic mechanisms of MOF, we may ultimately be able to design and time therapeutic interventions to prevent or reverse the deadly process.

Historical perspective

MOF has been called a "syndrome of surgical progress", as its emergence appears to have been a direct result of our ability to manage single-organ failures successfully. Significant refinements in surgical technique and perioperative care have often occurred during times of war, owing to the availability of larger, more concentrated experiences. For example, in the First World War, "wound shock", or a deficiency of circulating blood volume, was a common cause of death. Studies performed in the post-war period demonstrated the role of acute blood loss in the pathogenesis of traumatic shock, leading to more widespread use of blood transfusions [21]. Not surprisingly, the aggressive administration of blood in the Second World War was credited with the reduced early mortality from shock. However, reports at the end of the Second World War noted that many of the wounded went on to develop acute renal failure. This continued to be a problem during the Korean War. In fact, among those wounded in Korea who reached forward hospitals alive, renal failure was blamed for over 50% of later fatalities [127]. Basic scientific investigations supported the addition of crystalloid solutions to blood transfusions. More vigorous fluid resuscitation during the Vietnam War led to a 20- to 30-fold reduction in the incidence of renal failure compared with the Korean experience. However, a new problem came to the forefront in Vietnam: "shock lung"—the acute respiratory distress syndrome (ARDS) [8]. Of note, in accounts of the Korean conflict, there was virtually no mention of pulmonary problems. Advances in respiratory care, and particularly in mechanical ventilation, allowed more patients to survive ARDS. Today, while our ability to sustain patients on mechanical ventilation has improved, the number of patients dying with ARDS remains high; this is because the actual cause of death has shifted to MOF. The identification of MOF as a distinct entity dates back to 1973, when Tilney, Bailey and Morgan [128] described the progressive failure of organ systems in patients following repair of ruptured abdominal aortic aneurysms. Baue [15] first suggested there was a sequential pattern to the MOF syndrome. In 1977, Eiseman, Beart and Norton [40] at our institution described its clinical presentation and coined the term "multiple organ failure". Since that time, intensive research efforts have targeted the syndrome.

Multiple organ failure syndrome

Regardless of the inciting event, the syndrome of MOF generally follows a predictable course. Typically, ARDS is first, followed by renal and hepatic dysfunction. Myocardial failure is a later (and often preterminal) manifestation. The reason for the early appearance of pulmonary failure is unclear; it may reflect a lesser functional reserve of the lung compared with liver or kidneys, or it may suggest that our ability to detect pulmonary dysfunction is more sensitive. The time course of MOF is variable, as it may be affected by the nature of the initial insult as well as by pre-existing disease. We have recently recognized a bimodal pattern in the development of MOF in a large series of severely injured patients, with distinct characteristics of each group [91]. Early

Table 1 Multiple organ failure (MOF) score*

	Organ	Grade 1	Grade 2	Grade 3
A	Lung	ARDS score > 5†	ARDS score > 9	ARDS score > 13
B	Kidney	Creatinine > 1.8‡	Creatinine > 2.5	Creatinine > 5.0
C	Liver	Bilirubin > 2.0§	Bilirubin > 4.0	Bilirubin > 8.0
D	Heart	Minimal inotropes**	Moderate inotropes	High inotropes

*MOF score = grade (A+B+C+D) not due to chronic disease.

†See table 2 for ARDS score.

‡Creatinine (mg dl^{-1}).

§Bilirubin (not due to biliary obstruction or resolving haematoma) in mg dl^{-1}.

**Cardiac index < 3 litre min^{-1} m^{-2} requiring inotropic support: minimal = dopamine or dobutamine < 5 µg kg^{-1} min^{-1}; moderate = 5–15 µg kg^{-1} min^{-1}; high = > 15 µg kg^{-1} min^{-1}.

Table 2 Acute respiratory distress syndrome (ARDS) score*

	Parameter	Grade 1	Grade 2	Grade 3	Grade 4
A	Chest x-ray	Diffuse, mild interstitial consolidation	Diffuse, marked interstitial/mild airspace consolidation	Diffuse, moderate airspace consolidation	Diffuse, severe airspace consolidation
B	Pa_{O_2}/FI_{O_2} (torr)	175–250	125–174	80–124	< 80
C	Ve (litre min^{-1})	11–13	14–16	17–20	> 20
D	PEEP (cm H_2O)	6–9	10–13	14–17	> 17
E	Cstat (ml cm^{-1} H_2O)	40–50	30–39	17–20	< 20

Pa_{O_2}/FI_{O_2} = ratio of arterial oxygen tension to fractional inspired oxygen concentration; Ve = minute ventilation; PEEP = positive end-expiratory pressure; Cstat = static compliance.

*ARDS score = grade A (A+B+C+D+E) provided no clinical suspicion of pulmonary oedema.

MOF (occurring within 72 h of the initial insult) appears to be associated with more cardiac dysfunction, and indices of shock are the critical risk factors. In addition, it takes a rapid course: those patients who die, succumb faster. In contrast, late MOF (> 72 h after the initial insult) is associated with more hepatic dysfunction and advanced age. Infections appear to be more prominent in its pathogenesis, and non-surviving patients suffer a protracted course.

To identify organ failure more precisely, numerous scoring and classification schemes have been applied to MOF [42, 46, 64]; a discussion of them is beyond the scope of this review. When we initiated our National Institutes of Health (NIH) Specialized Centers of Research (SCOR) project in 1987, we developed an MOF score for the purpose of identifying MOF as an endpoint, objectively and reproducibly. We initially experienced difficulties in applying the score in a multicentre trial, and subsequently revised it [115]. Our MOF score is now based on easily obtainable measurements of pulmonary, renal, hepatic and cardiovascular function (tables 1 and 2). Individual organ failure is defined as a grade of 2 or higher, and MOF is defined as a score of 4 or more, 48 h after admission. We do not consider scores in the first 48 h because they may reflect reversible derangements induced by the inciting event or by incomplete resuscitation. Gastrointestinal, haematological, neurological and metabolic failure—included in the original score—were excluded from consideration because their definitions were subjective and, more importantly, they did not contribute substantially to identifying MOF. Applying the MOF score in our critically ill patients has greatly facilitated our clinical research efforts, particularly in identifying risk factors for MOF [116]. Consequently, we have been able to focus our basic research effort on the highest-risk patients, characterizing many of the physiological derangements associated with severe injury and correlating them with the progression to MOF. Further, we have been able to develop laboratory models to mimic severe injury *in vivo*, and manipulate the inflammatory response *in vitro*.

Pathogenesis of multiple organ failure

INFECTION AND MULTIPLE ORGAN FAILURE

Early reports of MOF implicated infection as the primary aetiological factor [109]. An influential paper by Fry and colleagues [46] in 1980 retrospectively reviewed 553 patients requiring emergent operations. Thirty-eight (7%) developed MOF; of these, 89% had sepsis, leading the investigators to conclude that MOF was a "fatal expression of uncontrolled infection". This study was pivotal in the subsequent adoption of an aggressive policy of mandatory laparotomy to drain intra-abdominal abscesses in MOF patients. This seemed a rational approach at the time, particularly since the primary experiences being reported were from urban trauma centres, in which penetrating injuries were frequently complicated by secondary infections. However, a provocative paper by Norton [98] in 1985 showed that drainage of intra-abdominal abscesses resulted in reversal of MOF in a dishearteningly small number of patients. Thus, it appeared that an abscess may promote MOF but was not necessary to perpetuate it. An alternative viewpoint was offered in reports from Europe around this time, which emphasized that a large number of patients with clinical sepsis could develop MOF and die without a focus of infection. Faist and colleagues [42] reviewed 433 trauma patients, of whom 8 % developed MOF; of these, only 59 % had sepsis. Goris and colleagues [50] examined the role of sepsis in MOF. Bacterial sepsis was confirmed in just 33 % of trauma patients, compared with 45 % of intra-abdominal sepsis (non-trauma) patients.

Continuing with the theme of infection as the aetiological agent of MOF, Marshall and colleagues [76] analysed nosocomial infections bacteriologically and concluded that the proximal gastrointestinal tract was the occult source of infection. Indeed, extensive basic research, employing a variety of rodent models, offered compelling evidence invoking translocation of bacteria or endotoxin as the common precipitating event for MOF after injury or haemorrhagic shock [12, 35, 73, 120]. However, considerable debate has centred around whether microbial translocation is a clinically important phenomenon [95]. We performed a prospective clinical trial to verify bacterial translocation in 29 patients sustaining major trauma [90]. In this patient population (with a 30 % incidence of MOF), we were unable to detect bacteria in either portal or systemic circulation within the first 5 days after injury. In addition, we found no elevations of tumour necrosis factor (TNF) to suggest endotoxaemia. Similar findings were reported by other contemporary investigators. Peitzman and colleagues [104] found no evidence of bacterial translocation in 25 injured patients, despite a mortality of 16 % and a 40 % major complication rate. Morales and colleagues [92] found no evidence of translocation in a porcine model of haemorrhagic shock. Additional evidence minimizing the contribution of translocation came from trials using selective gut decontamination to suppress intestinal aerobic flora (and thereby limit the translocation of microbes). This intervention has not proved beneficial in reducing MOF or mortality [28, 51]. Thus, while early studies correctly observed that infection with systemic sepsis can cause MOF, MOF frequently occurs in the absence of infection. Based on these findings, our investigations were redirected towards elucidating alternative mechanisms promoting the postinjury systemic inflammatory response syndrome (SIRS) and ultimately MOF.

SYSTEMIC INFLAMMATORY RESPONSE SYNDROME

The systemic clinical manifestations of Gram-negative bacterial sepsis can be mimicked by other infectious organisms, as well as by stimuli that lead to a prolonged and excessive inflammatory response. To standardize communication in this area, a consensus paper by the American College of Chest Physicians/Society of Critical Care Medicine proposed definitions pertaining to sepsis and organ failure [32]. The term "SIRS" refers to the inflammatory response to infectious or non-infectious processes. SIRS is defined as two or more of the following clinical conditions, independent of cause: (1) body temperature > 38 °C or < 36 °C; (2) heart rate > 90 beat/min; (3) tachypnoea, manifest by respiratory rate > 20 breaths/min or hyperventilation indicated by $Pa_{CO_2} < 32$ torr; (4) alteration of the white blood cell count with $> 12 \times 10^6$ cells/l or $< 4 \times 10^6$ cells/l. "Sepsis" refers to SIRS of an infectious origin. The recognition of SIRS independent of infection has stimulated several new hypotheses regarding the underlying mechanism of MOF. The focus of recent thought is that MOF represents the culmination of a generalized and excessive neuroendocrine, immune and inflammatory response to an insult—a modern "horror autotoxicus" [16].

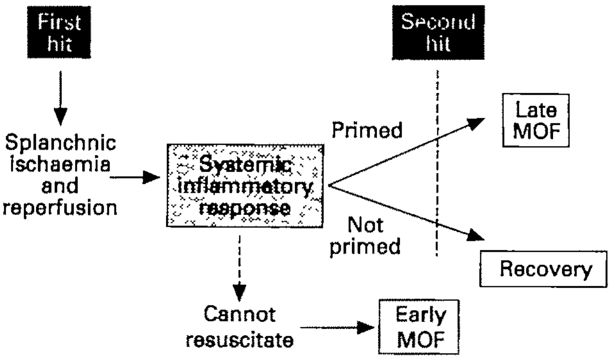

Figure 1 The "two-hit" model of postinjury multiple organ failure (MOF). The initial insult (first hit) causes splanchnic hypoperfusion, resulting in systemic inflammatory response syndrome. Some patients immediately progress to early MOF; others are "primed" such that a second hit results in progression to late MOF.

THE "TWO-HIT" MODEL OF MULTIPLE ORGAN FAILURE

The realization that the host is destroying itself, and is not being consumed by micro-organisms, shifted research efforts from the detection and treatment of infections to characterization and attenuation of the initial insult. Our SCOR project proposed a "two-hit" model of MOF several years ago (fig. 1). Briefly, an initial insult (the "first hit") "primes" the inflammatory system such that the response of the system to a second insult (the "second hit") is exaggerated. This exaggerated response can precipitate MOF. The correlate of this model at the cellular level is the priming and activation of polymorphonuclear leucocytes—neutrophils (PMN) [23]. The second hit may be virtually any insult, including infection, anaesthesia, an episode of hypotension, etc. In some cases, the patient suffers such a massive first hit that he or she deteriorates rapidly into MOF.

Our trauma research centre has examined the underlying pathophysiology of the first hit, and attempted to identify indicators of primed patients who are at risk for MOF after a second hit. A number of diverse clinical conditions have been reported to precede the progression to MOF (i.e. first hits); in general, the insults may be classified as infection, inadequate tissue perfusion, inflammation, or dead or injured tissue. Consequently, there are several existing hypotheses regarding what constitutes the first hit, although none have been accepted wholeheartedly. One prominent theory is the "gut hypothesis", which suggests that the gut is the "motor of MOF" [84].

Splanchnic ischaemia/reperfusion

The splanchnic circulation is particularly vulnerable to hypoperfusion. Several investigators have demonstrated that in low-flow states such as haemorrhagic shock, perfusion of the splanchnic bed decreases dramatically and out of proportion to the overall decrease in cardiac output [2, 11, 82]. Furthermore, the splanchnic circulation is the last to be restored after resuscitation. Gastric intramucosal pH measurements have a high specificity for predicting patient survival in the intensive care unit [38]. Maynard and colleagues [79] found gastric intramucosal pH to be an earlier and more reliable predictor of outcome than cardiac index, oxygen delivery or oxygen consumption, prompting Dantzker [34] to refer to the gastrointestinal tract as "the canary of the body".

The mechanism of disproportionate splanchnic vasoconstriction is probably multifactorial. Autonomic (neurally mediated α-adrenergic stimulation of postcapillary venous beds), humoral (vasopressin and angiotensin II), and local factors (prostaglandins $PGF_{2\alpha}$, PGB_2 and PGD_2, leukotrienes C_4 and D_4, some thromboxane analogues and nitric oxide inhibition) all appear to be involved. In addition, motor activity and luminal distension can cause hypoperfusion of intestinal segments [74, 103]. The relative contribution of each factor is unclear. Although there is increased sympathetic nervous system activity in low-flow states, disproportionate splanchnic vasoconstriction is not ameliorated by α-adrenergic block [82] or mesenteric arterial denervation [2]. In contrast, the vasoconstriction can be abrogated by pharmacological or surgical ablation of the renin–angiotensin axis, suggesting a primary role of the axis in mediating the effect [11].

Tissue ischaemia initiates a sequence of events that may ultimately lead to cellular dysfunction and necrosis. The primary mechanism is depletion of cellular energy stores and accumulation of toxic metabolites. Resumption of blood flow is necessary for cellular salvage; however, reperfusion of ischaemic tissues paradoxically creates more tissue injury. In fact, Parks and Granger [102] have shown that relatively little intestinal mucosal injury occurs during ischaemia compared with reperfusion. Interestingly, anoxic reperfusion of ischaemic tissues results in very little damage, suggesting that the formation of oxygen-derived cytotoxic products is critical in I/R injury [72, 105].

REACTIVE OXYGEN METABOLITES IN REPERFUSION INJURY

Molecular oxygen (O_2) can accept a total of four electrons to form water (H_2O); however, stepwise reduction of O_2 generates different species of oxidants. The univalent reduction of O_2 yields the superoxide anion radical (O_2^-). The cellular toxicity of O_2^- is attributed to its role as a precursor of more reactive species. Hydrogen peroxide (H_2O_2) is formed as a result of the divalent reduction of O_2, or the dismutation of O_2^-. The latter occurs spontaneously and rapidly in aqueous solution, so that the production of O_2^- is generally associated with the generation of H_2O_2.

Finally, through the Haber-Weiss reaction, O_2^- and H_2O_2 interact to produce the hydroxyl radical (•OH), the most potent known oxidizing agent [136]. The result of the formation of these reactive oxygen metabolites (ROM) is damage to membrane lipids, nucleic acids, enzymes and receptors, with impaired cellular function and eventual necrosis [121]. The formation of ROM after reperfusion has been detected using electron-spin resonance spectrometry [97] and chemiluminescence [129]. These studies demonstrate a burst of ROM formation immediately after reperfusion, lasting 2–5 min. Free radical scavengers such as superoxide dismutase (SOD) can suppress the respiratory burst. The ROM generated during reperfusion have been directly implicated in tissue injury. Increases in microvascular permeability induced by I/R can be attenuated by SOD, copper diisopropyl salicylate (an SOD mimetic), calatase (an enzyme that catalyses H_2O_2 disproportionately to H_2O and O_2), and non-enzymatic scavengers of •OH including dimethyl sulphoxide, dimethyl thiourea and mannitol [136].

XANTHINE OXIDASE IN REPERFUSION INJURY

Xanthine oxidase (XO) is the rate-limiting enzyme in nucleic acid degradation, through which all purines are channelled for terminal oxidation. XO can generate O_2^- and H_2O_2 during the oxidation of hypoxanthine or xanthine. In healthy, non-ischaemic cells XO exists predominantly as the NAD^+-dependent xanthine dehydrogenase (XD), which does not use O_2 as an electron acceptor and thus does not produce O_2^- or H_2O_2. During tissue ischaemia, XD is converted to XO [14]. In comparison with other tissues, the intestinal mucosa has a tremendous capacity to oxidize hypoxanthine via XO. In fact, in humans, liver and intestine have the highest XO activity of any tissue [52]. The role of XO in intestinal reperfusion injury has been directly assessed. The XO inhibitors allopurinol, oxypurinol and pterin aldehyde all attenuate I/R-induced microvascular permeability. In addition, XO inactivation by adminstration of a tungsten-supplemented, molybdenum-deficient diet (tungsten replaces molybdenum in the active site of XO, rendering it inactive) has the same effect [136].

NEUTROPHILS IN REPERFUSION INJURY

Neutrophils (PMN) represent another source of ROM. NADPH oxidase in PMN reduces O_2 to O_2^-. In addition, PMN-derived myeloperoxidase catalyses the formation of hypochlorous acid (HOCl) from chloride ions and H_2O_2. HOCl is approximately 100 times as reactive as H_2O_2 as an oxidizing and chlorinating agent. It reacts with primary amines to form N-chloro derivatives, potent oxidizing agents which are likely mediators of cellular injury [136].

The potential role of PMN in reperfusion injury has been studied extensively. PMN exist in high concentrations in intestinal mucosal tissue (10^6 PMN/g tissue) [52]. This population of cells is capable of producing enough O_2^- and cytotoxic enzymes (e.g. elastase, collagenase) to injure or destroy parenchymal and endothelial cells. Ischaemia and, to a greater degree, reperfusion of intestine lead to a large influx of PMN. Based on pretreatment with various compounds, it appears that ROM play a role in PMN recruitment [54, 125]. Hernandez and colleagues [55] demonstrated that PMN are the primary mediators of I/R-induced intestinal microvascular permeability. They further identified PMN–endothelial adhesion via the PMN CD18 membrane receptor as an essential component of I/R injury. Using intravital microscopy, Granger and colleagues [53] observed that I/R greatly exacerbates PMN-endothelial adhesion over ischaemia alone, and demonstrated that XO-derived ROM initiate the adherence of PMN to endothelium.

The above studies have provided a framework for intestinal I/R injury: I/R results in the generation of ROM which play a role in attracting PMN to the intestinal microvasculature, promoting adherence to the endothelium, and allowing PMN-mediated tissue injury with increased microvascular permeability. We became interested in this sequence of events as it related to distant organ injury.

Splanchnic ischaemia/reperfusion as a model of systemic inflammation

Although a number of inflammatory cascades have been incriminated in the pathogenesis of MOF, an attractive unifying concept is diffuse PMN-mediated tissue injury. The PMN is well equipped for cytotoxicity via oxygen dependent (NADPH oxidase) and independent (proteolytic enzymes) mechanisms, and PMN have been incriminated directly in the pathogenesis of ARDS and MOF [99, 126, 133]. PMN can be activated by I/R [25, 45, 49], and they have been demonstrated in distant organs following I/R insults [6, 118, 130]. Thus, we hypothesized that after injury splanchnic I/R creates a local environment that primes circulating PMN which mediate distant organ injury.

We developed a rodent model of splanchnic I/R [107]. In brief, adult, mature Sprague–Dawley rats (350–400 g) were anaesthetized and via a midline laparotomy the superior mesenteric artery (SMA) was occluded at its origin. After 45 min of intestinal ischaemia, the clamp was removed, the incision was closed and the animals were allowed to wake. The 45-min clamp time was based on preliminary studies demonstrating 100 % survival and no intestinal mucosal histological changes at 24 h. We found that splanchnic I/R results in reversible liver and lung injury (as measured by microvascular permeability). This effect was not seen in PMN-depleted rodents, implicating PMN in the injury. Work before this in our laboratory had shown that depletion of XO activity by tungsten diet decreased lung PMN accumulation following haemorrhagic shock [5]. We were interested in the role of XO in our I/R model, and repeated the experiments with the I/R insult. We found that XO inactivation, like PMN depletion, abrogated the effects of I/R on distant organs [108]. In attempting to sequence the events after splanchnic I/R, we identified XO activation as a proximal event, whose blockade attenuated splanchnic PMN accumulation, circulating PMN priming and lung injury [71].

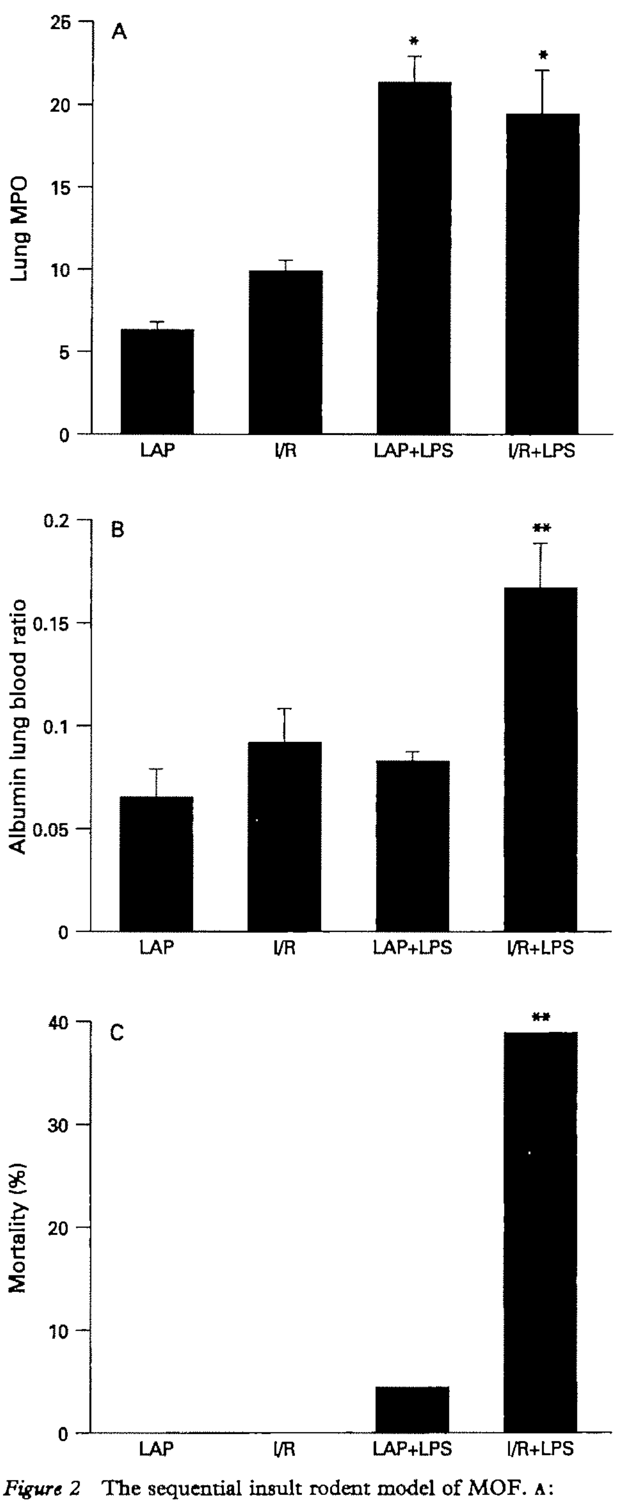

Figure 2 The sequential insult rodent model of MOF. A: Laparotomy (LAP) or laparotomy with splanchnic ischaemia and reperfusion (I/R) were performed alone, or followed in 6 h by lipopolysaccharide (LPS) (LAP+LPS or I/R+LPS). LPS resulting in polymorphonuclear leucocyte sequestration with or without I/R. Sequential results (I/R followed by LPS) resulted in increases in lung leak (B) and mortality (C). *Denotes difference from LAP and I/R; **denotes difference from LAP, I/R, and LAP+LPS ($P < 0.05$).

Clinical experience indicated that multiple insults (the two-hit model) were more typical of MOF.

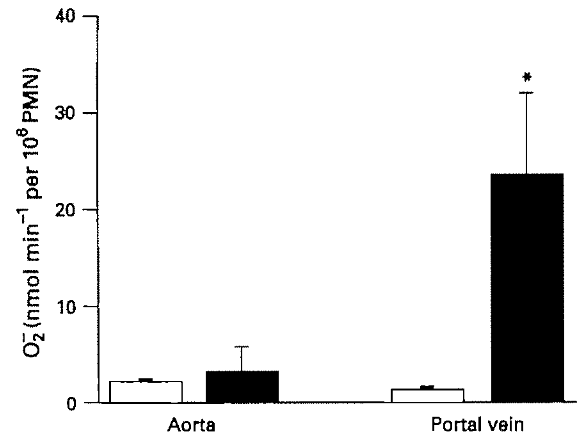

Figure 3 Priming of polymorphonuclear leucocytes (PMN) in the portal *vs* systemic circulation after splanchnic I/R, at 90 min of reperfusion. Priming measured as superoxide generation following formyl-methionyl-leucyl-phenylalanine (fMLP) stimulation. *Denotes difference from aortic samples. (□) −fMLP; (■) +fMLP.

Thus, our working hypothesis became that splanchnic I/R initially primes the systemic inflammatory cascade, and when followed by an activating stimulus during the vulnerable "primed" period, results in distant organ injury. To test this hypothesis, we developed a sequential insult model in which the priming event was splanchnic I/R, and the activating event was injection with low-dose endotoxin. Six hours into reperfusion, the study animals were administered low-dose bacterial lipopolysaccharide (LPS) (*Salmonella typhimurium*), 2.5 mg kg^{-1} i.p. The LPS dose was based on a dose which did not by itself produce lung leak. We found that PMN were sequestered in the lung after LPS administration, either with or without previous I/R insult. Lung injury was not seen after I/R or LPS alone but was caused by the sequential insults. Finally, there was a 39% mortality in the sequential insult group, compared with $\leqslant 4\%$ morality in all other study groups (fig. 2) [70]. In summary, a relatively brief period of splanchnic I/R appeared to prime the inflammatory response such that low dose LPS exposure during the vulnerable period activated the system, resulting in distant organ injury. Furthermore, splanchnic I/R promoted PMN sequestration in the lung, and the arrival of PMN correlated temporally with progressive endothelial dysfunction. Conversely, the mere presence of increased numbers of PMN (after LPS alone) was insufficient to produce lung injury.

Our hypothesis then became that splanchnic I/R provokes distal organ injury via a mechanism involving priming of circulating PMN in the reperfused splanchnic bed. Priming was measured as O_2^- generation stimulated by low dose formyl-methionyl-leucyl-phenylalanine (fMLP 10^{-6} mol litre^{-1}). In our I/R model, we had noted that circulating PMN become primed at 2 h of reperfusion [66]. To determine whether priming occurred in the splanchnic circulation, we measured priming of PMN drawn from the splanchnic inflow (aorta) as well as the splanchnic outflow (portal vein) after 90 min of reperfusion. We found primed PMN in the portal vein but not the aorta (fig. 3) [44]. Around this time, Johnston and colleagues [61] showed that mediators of gut origin are responsible for I/R-induced injury, and that bypassing the liver has no effect on the injury.

Our next series of studies focused on the mechanism of PMN priming in the splanchnic circulation. Although we had not found evidence of bacterial translocation in our severely injured patients who developed MOF [90], we were interested in whether LPS was involved in PMN priming in our I/R model. We measured LPS levels in the plasma of laparotomized rodents *vs* those subjected to splanchnic I/R, and found no difference. In addition, elimination of LPS by E5 monoclonal antibody had no effect on PMN priming after I/R [69]. As we had previously suspected, something other than LPS is responsible for PMN priming and activation after splanchnic I/R. We began our search for inflammatory mediators capable of PMN priming, which were generated in the gut.

Gut-derived mediators of neutrophil priming

Although numerous inflammatory mediators have been identified as contributors to SIRS and MOF, our investigations have identified two particular compounds as relevant gut-derived mediators of PMN priming: PAF and IL-6.

PLATELET-ACTIVATING FACTOR

Platelet-activating factor (PAF) is a biologically active phospholipid which is synthesized *de novo* continuously, but which may be generated to a greater degree via remodelling of membrane-bound lipids. Phospholipases catalyse the splitting of membrane phospholipids. Phospholipidase A_2 (PLA_2) is designated as such because it cleaves the fatty acid (Acyl) group from the middle (sn-2) carbon of the phospholipid's glycerol backbone [4]. If the sn-2 acyl group is arachidonate, eiconsanoid synthesis is initiated. When the remaining phospholipid has an *O*-alkyl ether in the sn-1 position and a phosphocholine moiety in the sn-3 position, lyso-PAF is formed and PAF synthesis is initiated by a calcium-dependent acetyltransferase. PLA_2 can be activated by ROM [29]; in addition, ROM inhibit PAF acetylhydrolase, the enzyme that catabolises PAF [3]. Given the high concentration of PLA_2 in intestinal mucosa, PLA_2 activation and subsequent PAF formation are a likely consequence of splanchnic I/R [4, 101].

PAF has many known pro-inflammatory effects, including PMN priming and PMN-endothelial adherence [7, 47, 58, 87, 111, 131]. Few clinical studies have actually documented increases in PAF concentrations after injury, in part because of the inherent logistic difficulties in its detection and quantitation. Nevertheless, there is compelling evidence involving PAF in postinjury hyperinflammation [24, 93. 106, 123, 124]. Furthermore, I/R-induced PMN adherence to endothelium can be

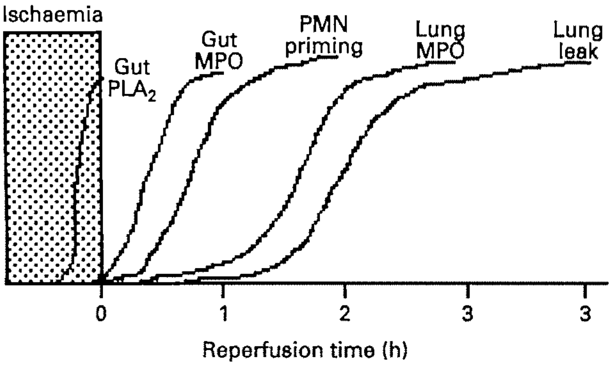

Figure 4 Temporal sequence of events pertinent to the pathophysiology of splanchnic I/R-induced distant organ injury, based on studies from our laboratory. Activation of intestinal phospholipase A_2 (PLA_2) during ischaemia is a proximal event; accumulation of polymorphonuclear leucocytes (PMN) in the gut precedes recovery of primed PMN from the circulation. PMN are sequestered in the lung, and then lung leak is noted. MPO = myeloperoxidase.

diminished by PAF-receptor antagonists [110, 135]. Our finding that PAF was responsible for PMN priming in patients after both thermal and mechanical trauma [106] prompted a series of laboratory investigations. Activation of gut PLA_2 was temporally correlated with PMN priming in our rodent mesenteric I/R model (fig. 4); inhibition of PLA_2 was protective against distant organ injury [68]. We subsequently confirmed PAF production in the distal small bowel after gut I/R, and a PAF-receptor antagonist inhibited PMN priming in this setting [63].

INTERLEUKIN 6

Interleukin 6 (IL-6) is considered an integral mediator of the physiological acute phase response to injury [27]; however, excessive and prolonged elevations of circulating IL-6 concentrations in patients after trauma, burns and elective surgery are associated with morbidity and mortality [9, 33, 39, 41, 85, 114]. The precise role of IL-6 in mediating adverse post-injury events remains ill-defined; moreover, the specific source and stimuli of IL-6 are not entirely clear. IL-6 is inducible in nearly every human tissue and cell type; numerous cytokines, growth factors, hormones, neuropeptides, leukotrienes and microbial products stimulate its production. The short half-life of IL-6 in serum (less than 1 h) combined with the fact that IL-6 is constantly detected in blood, suggests continuous production of IL-6. An intestinal source of IL-6 after surgery and trauma has been suggested. Baigrie and colleagues [10] found significantly higher elevations of IL-6 in inferior mesenteric veins than systemic veins during and after aortic cross-clamping in aortic surgery. Similarly, Wortel and colleagues [134] detected IL-6 in higher concentrations in portal *vs* peripheral venous blood in patients after pancreatic and hepatic resolutions. Deitch and colleagues [36] found higher IL-6 concentrations in portal *vs* cardiac blood after haemorrhagic shock in rats. Thus, IL-6 appears to be generated in the gut after systemic insults. In fact, Meyer and colleagues [86] have demonstrated IL-6 production in intestinal mucosa *in vivo*.

IL-6 is capable of promoting hyperinflammation and organ injury. It increases endothelial permeability in the absence of PMN [78]. In addition, accumulating evidence suggests that IL-6 mediates inflammation by modulating the functional repertoire of the mature PMN. Circumstantial evidence comes from a recent study showing coordinate increases in circulating concentrations of IL-6 and PMN elastase after aortic cross-clamping [62], raising the possibility that IL-6 may be involved in reperfusion injury. Oka and colleagues [100] demonstrated that patients with postoperative complications had higher concentrations of IL-6 than those without complications; furthermore, PMN priming for release of elastase was also higher in the cohort with complications. Redmond and colleagues [112] demonstrated that open cholecystectomy patients, shown to have higher IL-6 concentrations, had increased PMN chemotaxis and priming for O_2^- release compared with laparoscopic cholecystectomy patients. In addition, the open cholecystectomy group had more septic complications. We have studied the effects of IL-6 on PMN cytotoxic functions *in vitro*, and found that IL-6 can sensitize PMN to the effects of a subsequent inflammatory mediator [20]. IL-6 by itself does not prime PMN for O_2^- release; however, when quiescent PMN are incubated with IL-6 and then exposed to PAF, the PMN are primed for O_2^- release. The concentration of PAF required for this effect is 100-fold lower than that required to prime PMN without prior IL-6 stimulation. Mullen and colleagues [94] have similarly demonstrated synergy between IL-6 and TNF-α in PMN priming. IL-6 may also affect PMN-mediated inflammation by modulating apoptosis, or programmed cell death. PMN flux into the interstitial space is unidirectional, and PMN must meet their fate *in situ*. The physiological mechanism of obligatory PMN clearance is believed to be apoptosis. Senescent, apoptotic PMN initiate a signal prompting macrophage phagocytosis. This cytophagocytosis resolves inflammation without activation of the macrophage or exocytosis of cytotoxic PMN contents. Recently, this process has been identified as an important mechanism in the normal resolution of inflammatory processes and the limitation of inflammatory tissue injury. We have found that IL-6 delays PMN apoptosis, resulting in a larger population of non-apoptotic (surviving) PMN with a greater collective capacity for O_2^- production than untreated PMN [18]. The IL-6-mediated delay of PMN apoptosis could postpone the clearance of PMN from a site of inflammation, prolong release of ROM and proteolytic enzymes and aggravate PMN-mediated tissue injury and organ failure.

Although a direct causal link has not been made between IL-6 and MOF, there is an increasing body of evidence suggesting IL-6 is a pivotal component of the hyperinflammatory cytokine cascade driving SIRS. Simms and colleagues [119] studied patients with SIRS, and found that PMN had upregulated functions during SIRS; this upregulation persisted in patients who developed MOF but not in those who did not develop MOF. An anti-IL-6 antibody was effective in reducing PMN oxidative responses, implicating IL-6 as the primary PMN stimulant in the circulation. Gennari and colleagues [48] demonstrated that IL-6 neutralization decreased IL-6 concentrations and bacterial translocation, and improved bacterial killing; in addition, a correlation between IL-6 concentrations and survival time was observed.

While other cytokines (e.g. TNF and IL-1) may also be generated in the gut, IL-6 has been the one most consistently associated with adverse clinical outcomes. For example, we measured IL-6 and TNF concentrations in patients sustaining major trauma [90]. IL-6 concentrations were elevated immediately after injury, but TNF concentrations were not higher than uninjured controls at any time. Hoch and colleagues [57] found elevations of IL-6 and IL-8 in proportion to the severity of injury in trauma patients, but detected no endotoxin or IL-1α, and no elevations of TNF-α. Meade and colleagues [83] similarly found elevated concentrations of IL-6 and IL-8 after injury, but could not detect IL-1β, TNF-α or endotoxin at any time. In this study, both IL-6 and IL-8 concentrations remained elevated for more prolonged periods in patients who developed ARDS. In patients undergoing elective surgery, DiPadova and colleagues [37] found early increases in IL-6 after surgery, but did not see increases in IL-1 or TNF. In an animal model of I/R injury, Cipolle and colleagues [31] found IL-6 but not TNF after reperfusion. Marty and colleagues [77] showed that IL-6 concentrations were higher in non-survivors than surviving MOF patients, and that IL-6 elevations were similar in MOF of septic and non-septic origin. In liver transplant patients with MOF and suspected bacterial infections, Rosenbloom and colleagues [113] found IL-6, but not IL-1β or TNF, to correlate with organ failure.

Thus, there is a great deal of evidence for the critical involvement of IL-6 in hyperinflammation after injury. IL-6 appears to exert its effects via a PAF mechanism [17], and actually stimulates PMN to produce PAF [19]. Clearly, the next step in the study of IL-6 is to attempt to inhibit it in a splanchnic I/R model.

Mechanisms of distant organ injury

Our trauma research centre programme has recently focused on the mechanisms involved in distant organ injury. Presuming primed PMN exiting the splanchnic circulation are the mediators of distant organ injury, we have been interested in the interactions involved in PMN-mediated organ dysfunction. PMN-endothelial interactions are pivotal in tissue injury. Conceptually, there are at least three distinguishable phases of PMN-endothelial interactions, which involve different families of adhesion molecules [26]. The first is a low-affinity process, thought to be mediated by endothelial expression of selections (E, P and L), which produces rolling of PMN along the endothelium. The second phase is high-affinity, firm adhesion of PMN, mediated primarily by intercellular adhesion molecule (ICAM)-1 on the endothelium and the CD11/CD18 (β_2-integrin) complex on the PMN. ICAM-1 is also directly involved in the third phase, transendothelial migration. Blockade of the neutrophil CD11b receptor has been shown to be effective in reducing liver and lung injury after I/R [56, 67]. We have identified ICAM-1 as a pivotal regulator of PMN-mediated cytotoxicity *in vitro* [13], and several investigative groups have demonstrated a role for ICAM-1, in I/R-induced injury [43, 96, 122, 132]. Finally, recent evidence has implicated both IL-6 and PAF in upregulating ICAM-1 after I/R injury [30, 75].

Future directions

The data reviewed here strongly implicate splanchnic I/R in the genesis of malignant hyperinflammation resulting in MOF. The precise mechanistic events and relevant temporal associations remain to be elucidated. Until we develop agents to interfere with the inflammatory cascade, we must focus on prevention and supportive care. The principles of aggressive resuscitation [88], early fracture fixation and tissue debridement [22], and enteral nutritional support with immune-enhancing diets [89] have all been shown to be beneficial in attenuating the inflammatory response and MOF. Resuscitation should be targeted towards augmenting the splanchnic circulation. Recently, Ivatury and colleagues [59] showed that resuscitation of patients to supranormal levels of oxygen delivery and consumption did not consistently normalize gastric mucosal pH; however, when normalization of gastric mucosal pH was used as an endpoint of resuscitation, there was improved survival. This suggests that direct monitoring of the splanchnic circulation is preferable to systemic goal-oriented resuscitation. Low-dose dopexamine may prove a useful adjunct to augment splanchnic perfusion [80]. A final therapeutic intervention that may prove beneficial is the administration of inhaled nitric oxide (NO•). Jacob and colleagues [60] have found that trauma patients have inhibited NO• production. NO• has been used with increasing enthusiasm in the treatment of refractory ARDS [81]. Its ability to selectively vasodilate ventilated segments' of lung improves ventilation: perfusion matching. In addition, NO• has been shown to attenuate I/R-induced lung injury, presumably by inhibiting PMN influx into the lungs [1]. We have shown that NO• reduces endothelial expression of ICAM-1 (unpublished data), providing a potential protective mechanism from I/R-induced lung injury. Thus, interventions to improve splanchnic perfusion in the postinjury period, and to attenuate the systemic inflammatory response to injury, are going to be critical in preventing MOF and improving patient outcome.

Determinants of intestinal barrier failure in critical illness

J. S. Aranow and M. P. Fink

The gut serves not only as a physiological portal for the entry of water and nutrients into the body, but also as a barrier limiting the systemic absorption of intraluminal microbes, microbial products, or both. Evidence exists to support the view that trauma, sepsis or other critical illnesses lead to derangements in the barrier function of the gut. One potential consequence of deranged barrier function is bloodstream invasion by gut-derived pathogens, leading to "primary" bacteraemias or fungaemias, or even metastatic infections.

Another consequence of gut barrier dysfunction might be a several step process leading to a poorly controlled systemic inflammatory response and organ system failure. In the first step of this postulated pathophysiological process, microbes or toxins passively diffuse or are actively transported out of the lumen of the gut into submucosal tissues. In step two, these microbes or toxins activate immune cells in tissues or organs, which are "downstream" from the mucosa (e.g. Kuppfer cells in the liver; macrophages in the lamina propria of the gut, Peyer's patches or mesenteric lymph nodes). In the third step, the activated immune cells release various inflammatory mediators (cytokines, nitric oxide, eicosanoids, platelet activating factor), which have been implicated as being important in the pathogenesis of multiple organ dysfunction. The hypothesis that the gut is an endogenous source of pro-inflammatory agents is attractive because it might explain why signs and symptoms of sepsis, such as fever, leucocytosis, hypermetabolism and organ system dysfunction, frequently are present in critically ill patients, even in the absence of a well-defined focus of infection [42, 91, 92].

Components of the intestinal barrier

Intestinal barrier function depends upon a stratified system of defences. These defences include the normal microbiological flora of the gut, enteric secretions, peristalsis, gut-associated immune cells and the epithelium itself.

Under normal conditions, anaerobic organisms, growing as a carpet on the mucosal surfaces of the gut, limit colonization and overgrowth of other potentially invasive microbes [148]. However, in critically ill patients, possibly because of the administration of broad-spectrum antibiotics, the gut commonly becomes colonized by potentially pathogenic facultative Gram-negative bacilli, Gram-positive cocci and fungi [92, 93]. These organisms are believed to express specialized virulence factors enabling mucosal adherence and penetration [136].

Mucins, secreted by epithelial goblet cells, create a protective viscous gel that hampers bacterial penetration [148]. In addition, active Cl^- transport by epithelial cells promotes intraluminal fluid flux that washes away harmful agents [94]. Upregulation of mucosal Cl^- secretion occurs rapidly after ischaemic [95] or toxic [94] insults, or both, through a host of autocrine, paracrine and, perhaps, hormonal mechanisms. Additionally, mucosal secretions are rich in IgA antibodies that bind and aggregate bacteria [3, 4, 136] and thereby aid in preventing adherence to the mucosa and subsequent trans-epithelial invasion.

As the largest immunological organ of the body, the intestine contains numerous immunoreactive cells, including various subtypes of B- and T-lymphocytes, plasma cells, macrophages, neutrophils, Paneth cells and specialized "M cells" [8, 65]. Together these cells are thought to help prevent systemic infection by lumenally derived invasive microbes. The gut associated lymphoid tissue (GALT) consists of three distinct populations: Peyer's patches, immunocytes within the lamina propria, and interepithelial lymphocytes (IEL).

Found throughout the length of the small intestine, Peyer's patches are mucosal and submucosal lymphoid follicles that are the site of B-cell differentiation and immunoglobulin (IgA) class commitment [8, 65]. A proportion of these B-lymphocytes eventually migrate to the lamina propria, where they are critical in producing IgA that is secreted transcellularly by the epithelial cells. Antigen priming in intestinal lymphoid follicles produces selective humoral responses by stimulating clonal B-cell growth and migration to local as well as systemic sites. This function is facilitated by specialized epithelial cells, termed "M cells" [144], which selectively expose underlying lymphoid aggregates to luminal antigens thereby allowing continuous priming of lymphocytic defences.

IEL and lamina propria lymphocytes are predominately T-cells [8, 21]. These two populations

differ in phenotype and purpose. IEL predominantly express the CD8 cell surface marker and display cytolytic activity. As the first T-cells exposed to luminal antigens, their defensive role against microbial invasion is an active one. Exposure to infiltrating pathogens triggers both direct cytolytic activity as well as the release of cytokines that stimulate antigen-specific immune responses (IL-5) and epithelial growth (TGF-β). In contrast with IEL, lamina propria T-cells primarily express CD4 antigen and act as facilitators of inflammation and epithelial defences [8]. Activated by specific antigenic recognition, these cells turn on a cascade of protective reactions via cytokines.

The most critical barrier against systemic absorption of intraluminal microbes and microbial products is the epithelium *per se*. Structurally, the intestine is comprised of a single layered columnar epithelium arranged into villus and crypt components. Specialized cell–cell junctional complexes allow for selective paracellular permeability (tight junctions) [83], maintain intercellular adhesion (intermediate junctions and desmosomes) [131] and permit intercellular communication (gap junctions) [166]. The zonula occludens is a circumferential band of apical tight junctions that limits paracellular passage of ions and fluid. Under normal circumstances, tight junctions exclude passive movement of hydrophilic non-charged compounds with a molecular radius > 11.5 Å [83]. Substances that are therefore prevented from paracellular transepithelial movement include lipopolysaccharide (LPS) [149] and a variety of other bacterial-derived proinflammatory substances, such as formyl-methionyl-leucyl-phenylalanine (FMLP) [22] and peptidoglycan-polysaccharides [77], which are present in high concentration within the lumen of the distal small intestine and colon.

Assessment of intestinal mucosal barrier function

In clinical and experimental studies, the integrity of the gut mucosal barrier has been assessed using two very different approaches. One method estimates the degree of transmucosal movement of bacterial or fungal pathogens from the intestinal lumen into the vascular or lymphatic systems, a process referred to as *microbial translocation*. The second method quantitates the *permeability* of the gut to various water-soluble probes.

Microbial translocation does not necessarily imply the loss of epithelial integrity. Under some conditions, translocation in experimental animals subjected to a major stress (e.g. haemorrhage or endotoxaemia) appears to occur via tiny breaks in the continuity of the mucosal epithelial sheet [28, 31]. However, for the most part, translocation is a transcellular rather than a paracellular process [2, 155, 158, 159]. Moreover, in many experimental studies, the extent of translocation is quantitated by enumerating viable colony-forming units (CFU) in mesenteric lymph nodes (MLN) or other organs. However, data using radioactively labelled lumenal bacteria indicate that this approach vastly underestimates the extent of translocation, because most microbes breaching the epithelial barrier are killed [40]. Increases in "translocation" evidenced by increases in CFU in MLN or other organs are predominantly the result of decreased killing rather than increased transepithelial penetration.

Normally, the healthy intestinal mucosa manifests a very low basal level of permeability to large and middle-sized hydrophilic molecules. Systemic uptake of luminally placed water-soluble non-charged compounds such as mono- and disaccharides (e.g. rhamanose and lactulose), radiolabelled organic acid-transition metal complexes (e.g. chromium ehthylenediaminetetra-acetate [^{51}Cr-EDTA]), synthetic polymers (polyethylene glycol) or radiolabelled proteins (albumin) can be used to quantitate the rate of transepithelial flux. In such studies, two probes are commonly employed. One probe (e.g. mannitol) typically consists of a relatively small molecule which permeates moderately well through even normal mucosa. A second probe (e.g. lactulose) consists of a larger molecule, which permeates the normal mucosa only minimally. Probes which are non-metabolisable are chosen, and absorption of the probes is determined by measuring concentrations in plasma or urine. By measuring the *differential* concentrations of two probes, it is possible to remove confounding effects related to changes in intestinal motility (or renal function). Because the zonula occludens restricts intercellular passage of these probes in the luminal as well as vascular direction, permeability can also be assessed in animal models by measuring luminal concentrations of these probes after intravascular administration [35, 59].

Evidence for and against intestinal barrier dysfunction in critically ill humans

Convincing evidence of microbial translocation has been documented in humans under certain conditions. Deitch showed that viable enteric organisms frequently can be isolated from cultures of mesenteric lymph nodes obtained at laparotomy from patients with small bowel obstruction [26]. Similar results were obtained by Ambrose and colleagues in a study of patients undergoing abdominal operations for Crohn's disease [5]. van Goor and colleagues isolated bacteria in mesenteric lymph nodes from 11 of 21 brain-dead organ donors with anatomically intact gastrointestinal tracts [150]. Sedman and colleagues found evidence of translocation to mesenteric lymph nodes in 10.3% of 267 patients undergoing general surgical procedures [132].

Braithwaite and colleagues used immunofluorescent staining of *Escherichia coli*-derived β-galactosidase (rather than standard microbiological methods) to document the presence of bacteria in macrophages in mesenteric lymph node specimens from every one of 20 trauma patients [13]. Unfortunately, in this study, samples from normal controls were not obtained and, therefore, it is unclear whether this represents a normal or a pathological occurrence. Reed and colleagues used both standard microbiological methods and electron microscopy to demonstrate bacteria in mesenteric lymph nodes from trauma victims [120]. As in the study by Braithwaite and colleagues already cited, samples from normal individuals were not studied. Certainly the most dramatic evidence that translocation can occur in humans comes in the form of a report by Krause, Matheis and Wulf, who documented that oral ingestion of a suspension of viable *C. albicans* resulted in transient fungaemia and funguria in a normal volunteer [70]. None of these studies, however, has demonstrated a correlation between the presence of viable (or non-viable) organisms in mesenteric nodes (or blood) and the development of multiple organ dysfunction syndrome (MODS).

Rush and colleagues showed a high incidence of bacteraemia and endotoxaemia in blood samples obtained from patients with haemorrhagic shock [127]. Since the samples were obtained within minutes after presentation to the emergency department, the development of bacteraemia in these patients presumably was not due to hospital-acquired infection. Interestingly, most of the isolates in this study were Gram-positive, rather than the enteric Gram-negative bacilli, which are most commonly isolated in studies of bacterial translocation using animal models of haemorrhagic shock. Thus, the implications of the findings obtained by Rush's group remain uncertain.

Winchurch, Thupari and Munster have shown that endotoxin is detectable in plasma samples obtained within 24 h after the time of injury from victims of thermal trauma [165]. Moreover, these workers have shown that the degree of endotoxaemia correlates with the magnitude of the injury. In a recent report from this group, however, it was shown that prophylactic treatment with an endotoxin-neutralizing antibiotic (polymyxin B) could lower the concentrations of circulating endotoxin detected in burns patients, but that this treatment effect was not associated with a lessening in mortality or with the concentrations of a cytokine (IL-6) in plasma [104]. Thus, Winchurch, Thupari and Munster concluded that the presence of endotoxaemia in burns patients may be an epiphenomenon rather than a primary factor leading to organ dysfunction.

Two other recent studies of trauma victims failed to validate the notion that bacterial translocation is increased in one important subpopulation of critically ill patients, namely those with multiple trauma. Moore and colleagues [102] were unable to detect elevated endotoxin concentrations in portal venous or systemic blood samples obtained over the first 5 days of hospitalization from 20 victims of major abdominal trauma, even though 60 % of the patients were in shock at the time of presentation and six of the subjects developed MODS. Although nine (2 %) of 424 systemic and portal venous blood cultures were positive over the 5-day period of observation, many of the isolates were probable contaminants. Cultures of ileocolic lymph nodes were positive in four of 12 cases, although in one case the isolated organism (*S. epidermidis*) was probably a contaminant.

Peitzman and coworkers [115] obtained biopsies of mesenteric lymph nodes at the time of coeliotomy from 25 trauma patients. Although 40 % of the trauma patients had one or more major complications, including adult respiratory distress syndrome (ARDS), serious pulmonary infections, and Gram-negative bacteraemia, all of the lymph node cultures were sterile. As a control for technique, the authors of this study also cultured lymph nodes obtained from patients with primary gastrointestinal tract diseases, and in three of four cases, were able to isolate enteric organisms. Thus, these two studies must be viewed as casting doubt on the idea that translocation of gut-derived bacteria or endotoxin plays a crucial role in the development of serious complications, at least in victims of major trauma.

During the past several years, a number of studies have documented the presence of gut mucosal hyperpermeability in human volunteers challenged with tiny doses of endotoxin [109], or patients with a variety of critical illnesses [27, 51, 110, 124, 125, 128, 170]. However, just as is the case for translocation, data are lacking to show that the presence of hyperpermeability is associated with or predicts the development of MODS.

Despite the "negative" studies just cited, the notion that the gut is somehow a pivotal organ in critical illness remains viable because of other circumstantial evidence from clinical studies. Certainly, it is well established that septic complications are diminished by providing early enteral nutrition to trauma patients [74, 101]. In addition, colonization of the proximal gastrointestinal tract with certain pathogens, particularly *Pseudomonas aeruginosa* and coagulase-negative *Staphylococcus*, is associated with subsequent development of intensive care unit-acquired infections caused by these same organisms [92, 93]. Thus, the role of the gut as a "motor of multiple organ failure" remains a controversial but tenable hypothesis.

Pathophysiological mechanisms responsible for gut barrier failure

The patholophysiological mechanisms responsible for gut barrier dysfunction in critically ill humans remain to be elucidated. Given the complex nature of the gut barrier, however, it seems probable that no single mechanism can explain all aspects of barrier dysfunction or all cases of barrier dysfunction precipitated by different causes.

MUCOSAL HYPOXIA

In general, the rate of oxygen consumption ($V\text{O}_2$) by tissues is determined by the metabolic demand and not by oxygen delivery ($D\text{O}_2$); this is a statement of Pflüger's law. Certain pathophysiological processes can, however, reduce $D\text{O}_2$ below a critical value ($D\text{O}_{2\text{crit}}$) such that $V\text{O}_2$ becomes supply-dependent [57]. Supply-dependency of $V\text{O}_2$ can occur as a result of tissue hypoperfusion, arterial hypoxaemia or anaemia. Hypermetabolism, secondary to sepsis and other critical illnesses, necessitates higher $V\text{O}_2$, and thereby a higher $D\text{O}_{2\text{crit}}$ [52]. Alone or in combination, these factors may limit intracellular $P\text{O}_2$ to levels inadequate to support normal mitochondrial respiration. There are two important effects of supply-dependent mitochondrial respiration. First, glycolytic metabolic rate is increased in an effort to preserve adequate intracellular concentrations of adenosine triphosphate (ATP) by substrate level phosphorylation of adenosine diphosphate (ADP). In contrast with oxidative phosphorylation, substrate level phosphorylation is associated with the production of protons; i.e. enhanced glycolytic rate leads to intracellular acidosis [100]. Second, if mitochondrial respiration is sufficiently limited, then intracellular concentrations of ATP are depleted. As will be discussed below, both intracellular acidosis and ATP depletion can lead to increases in intestinal epithelial permeability.

In the clinical setting, the most likely cause of intestinal mucosal hypoxia is mesenteric hypoperfusion. The architecture of the microcirculation of the intestinal villi may act to increase the susceptibility of the epithelium to hypoxic injury because of inadequate perfusion. Each villus is supplied by a single central arteriole, which is surrounded by an arbor of draining venules. Probably as a result of both counter current arteriovenous diffusional shunting of oxygen as well as consumption of oxygen by cells along the length of the villus, the tissue $P\text{O}_2$ at the tips of villi is low even under normal conditions. During low flow states, these conditions are exacerbated, further increasing the likelihood of supply-dependency of oxygen uptake [81, 82, 133].

Another factor which may predispose the villous epithelium to ischaemic injury during low-flow states is "plasma skimming" [67]. This phenomenon occurs because the nutrient arterioles supplying each villus originate at right angles to the parent artery. Since erythrocytes tend to cluster away from the walls of arteries, this architecture leads to relative haemodilution (and reduced oxygen carrying capacity) in the blood perfusing villous arterioles.

Two common conditions, which are likely to induce marked mesenteric ischaemia in critically ill patients, are haemorrhage and cardiogenic shock [17, 97, 98, 122]. Studies using animal models have documented that global decreases in cardiac output because of haemorrhage or cardiac tamponade lead to activation of the renin-angiotensin axis, which, in turn, triggers a dramatic increase in mesenteric arteriolar resistance [17, 97, 122]. Splanchnic hypoperfusion also has been reported in animal models after thermal injury [61, 103].

Sepsis is another common condition, which may be associated with mesenteric hypoperfusion. In contradistinction to haemorrhage or cardiogenic shock, however, the effects of sepsis on mesenteric (or mucosal) perfusion and oxygenation are poorly understood. Total hepatosplanchnic perfusion is elevated in humans with compensated sepsis [25, 48, 163]. Data are lacking regarding the effects of septic shock in humans on mesenteric and, particularly, intestinal mucosal perfusion.

We [36, 37, 130] and others [6, 119, 138, 161, 167] have documented that mesenteric perfusion is compromised in experimental models of sepsis and septic shock. Interestingly, however, we have never been able to document a decrease in transmesenteric $V\text{O}_2$ in endotoxaemic pigs [36, 37, 130]. Other investigators have reported similar findings [7, 119, 151]. In other words, transmesenteric oxygen extraction seems to be increased sufficiently in sepsis to maintain normal (or even elevated) levels of $V\text{O}_2$. Nevertheless, ileal mucosal acidosis is a characteristic feature of sepsis in experimental animals [36, 37, 119, 130]. Gastric mucosal acidosis occurs commonly in septic patients [49, 88, 135].

The development of gastrointestinal mucosal acidosis in sepsis, whether in animals models or patients, has been interpreted as evidence of gut epithelial hypoxia. However, normalization of superior mesenteric arterial blood flow ameliorates but does not completely normalize endotoxin-induced mucosal acidosis in pigs [36], a finding which suggests that mechanisms other than, or in addition to, mucosal ischaemia might contribute to tissue acidosis in sepsis. To further investigate this issue, we recently conducted an experimental study using a resuscitated, normodynamic pig model of endotoxaemic shock [152]. Mucosal oxygenation was measured directly using an array of eight Clark-type tissue $P\text{O}_2$ microelectrodes. Mucosal perfusion and acidosis were measured by laser Doppler flowmetry and intraluminal tonometry, respectively. After infusion of endotoxin, pigs developed ileal mucosal acidosis despite the absence of any significant change in mucosal blood flow and a significant *increase* in mucosal oxygen tension ($P\text{m}_{\text{O}_2}$). These observations are consistent with previous findings obtained by Hurtado and colleagues, who showed that lactic acidosis develops in skeletal muscle of septic rabbits despite normal tissue oxygenation [62]. Although an unexpected finding, the increase in $P\text{m}_{\text{O}_2}$ induced by endotoxin can be explained on the basis of the Bohr effect (i.e. an increased unloading of oxygen from haemoglobin as a result of acidosis) [75].

OXIDANT STRESS

Oxidants have been implicated in a variety of causes of intestinal barrier dysfunction. In experimental animals, intestinal ischaemia followed by reperfusion leads to mucosal hyperpermeability and biochemical evidence of oxidant stress [44, 45]. During the reperfusion phase, spin trapping techniques have been used to demonstrate the formation of free radicals [108]. There are two main sources of reactive oxygen metabolites (ROM) in intestinal ischaemia/reperfusion: (1) the reaction catalysed by xanthine oxidase and (2) the reaction catalysed by NADPH oxidase in neutrophils sequestered in the intestinal microvasculature. Agents which scavenge ROM or inhibit xanthine oxidase have been shown to ameliorate derangements in intestinal barrier function after intestinal ischaemia/reperfusion [112]. These strategies also have been shown to have salutary effects on barrier function in animals subjected to haemorrhage [28, 29] or systemic inflammation [30, 32, 85].

The mechanisms whereby oxidants impair barrier function are not well understood. In various *in vitro* models, however, oxidants, such as hydrogen peroxide (H_2O_2) or superoxide radical ($O_2^-\cdot$) have been shown to increase the permeability of epithelial [160] or endothelial [55] monolayers, and also disrupt the cytoskeleton (by promoting excessive actin polymerization) [55, 56]. Although most research related to alterations in epithelial (or endothelial) permeability and the actin-based cytoskeleton have focused on the paracellular pathway, it is plausible that cytoskeletal derangements also promote increased endo- and transcytosis. Sundqvist and Liu reported that endocytosis of FITC-dextran (70000 Da) is promoted when cultured endothelial monolayers are incubated with H_2O_2, an oxidant known to cause cytoskeletal destabilization [141]. Bhalla and Crocker reported that exposure of tracheal epithelial cells to ozone, another potent oxidant, promotes vesicular transcytosis of a macromolecule (horseradish peroxidase) [9]. Thus oxidant-induced epithelial damage might promote barrier dysfunction via transcellular as well as paracellular pathways.

ROM can lead to ATP depletion [53, 54, 164]. As will be discussed below, ATP depletion is another potential factor contributing to epithelial barrier dysfunction. The mechanisms responsible for oxidant-mediated ATP depletion probably include inhibition of glyceraldehyde-3-phosphate dehydrogenase (in the glycolytic pathway) and inhibition of mitochondrial phosphorylation of ADP [64].

MUCOSAL ACIDOSIS

In an effort to maintain adequate energy levels, hypoxic cells increase their rate of anaerobic metabolism (i.e. glycolysis). In contradistinction to oxidative phosphorylation, substrate level phosphorylation of ADP during glycolysis leads to a net release of protons. Under anaerobic conditions, there is net formation of two moles of H^+ per mole of glucose metabolized (at physiological pH) [100]. Since anaerobic metabolism is less efficient than oxidative metabolism for generating high-energy compounds, hypoxia results in ATP depletion. In sepsis, tissue acidosis can occur even in the absence of hypoperfusion or hypoxia [60, 152]. Sepsis downregulates the activity of pyruvate dehydrogenase (PDH), the enzyme complex catalysing the first irreversible step in the mitochondrial oxidative pathway [153]. The shift of PDH to its inactive form in sepsis fosters increased flux through the glycolytic pathway without a commensurate increase in mitochondrial oxidative phosphorylation. Glycolytic flux also may be increased in sepsis as a result of increased availability of glucose transporters on the surface of cells [169].

Since acidosis is an inevitable consequence of cellular hypoxia, tissue pH might be a useful variable to monitor in critically ill patients. Indeed, low gastric intramural pH has been shown to predict the development of MODS, mortality, or both in critically ill patients [23, 34, 39, 50, 96, 126, 168]. Interestingly, in a recent study of the effects of intestinal ischaemia induced by systemic endotoxaemic or partial mechanical occlusion of the mesenteric artery in pigs, we noted that there was a strong correlation between the degree of mucosal tissue acidosis and the degree of ileal mucosal hyperpermeability induced by these perturbations [130]. This finding suggested to us that the adverse effects of ischaemia on intestinal epithelial permeability might be related to the resultant derangements in tissue pH rather than simply the changes in tissue oxygenation *per se*. In an effort to further investigate this possibility, we employed a porcine preparation to examine the effects of mucosal acidosis induced by deliberately increasing arterial carbon dioxide tension, and observed a substantial increase in ileal epithelial permeability, even in the absence of findings indicative of mucosal ischaemia or dysoxia [130]. In other studies, using cultured Caco-2_{BBe} cells as a model of the intestinal epithelium, we have shown that acidosis similarly increases permeability *in vitro* [unpublished observations].

The mechanism(s) whereby acidosis promotes epithelial hyperpermeability are unknown. It has been established, however, that acidosis can promote the formation of oxidants. A number of studies have shown that acidosis promotes lipid peroxidation [14, 19, 105, 121, 134] or other manifestations [111] of oxidant-mediated damage in cells. Acidosis promotes mobilization of free iron from intracellular stores [15, 113], and evidence has been presented supporting the view that oxidant stress under conditions of acidosis depends, at least in part, on iron delocalization [113]. Recent findings [123] suggest that another mechanism whereby acidosis enhances oxidant-mediated damage is inhibition of two key enzymes: glutathione reductase, which is required to regenerate reduced glutathione (GSH); and glutathione peroxidase, which uses GSH to convert H_2O_2 to water.

Another way that acidosis might alter epithelial permeability is increasing intracellular calcium concentration ($[Ca^{2+}]_i$) [18]. Possible mechanisms for the tendency of low pH_i to increase $[Ca^{2+}]_i$ in epithelial cells include increased mitochondrial Ca^{2+}–H^+ exchange, modulation of Ca^{2+} flux into the smooth ER, and activation of a pH-dependent plasma membrane Ca^{2+} channel [18]. Elevations in *intracellular* $[Ca^{2+}]$ loosen tight junctions and increase intestinal epithelial permeability. In hepatocytes, paracellular permeability is increased by a number of agents which increase $[Ca^{2+}]_i$, including: certain hormones (e.g. vasopressin) [80], a calcium ionophore (A23187) [66], and a calcium-mobilizing agent (tBuGHQ) [38]. In cultured MDCK (renal epithelial) monolayers, exposure to A23187 increases permeability [116]. The effects of increased $[Ca^{2+}]_i$ on intestinal epithelial permeability have not been investigated.

ATP DEPLETION

As noted above, ATP depletion is a consequence of impaired mitochondrial function, the result of intracellular hypoxia. ATP depletion can also be caused by oxidant stress, leading to inhibition of glyceraldehyde-3-phosphate dehydrogenase (in the glycolytic pathway) and inhibition of mitochondrial phosphorylation of ADP [64]. Acidosis, in a form of positive feedback, can also promote ATP depletion

[140], perhaps by inhibiting the rate-limiting phosphofructokinase step in glycolysis [20, 145] or via other poorly understood mechanisms [140].

In order to investigate the role of ATP depletion as a factor leading to intestinal hyperpermeability we recently studied the effects of chronic hypoxia or glycolytic inhibition with 2-deoxyglucose (2-DOG) on Caco-2_{BBe} monolayers [146]. In both scenarios, we found that relatively minor reductions ($< 30\%$) in ATP content were sufficient to increase the permeability of Caco-2_{BBe} monolayers. The mechanism appears to involve derangements in the actin-based cytoskeleton, since laser confocal micrographs using rhodamine-phalloidin to stain polymerized (F) actin demonstrated perijunctional condensation of actin filaments after prolonged 2-DOG exposure.

Although it is well established that ATP depletion increases epithelial [71, 76, 87, 146] and endothelial permeability [157], the precise mechanism(s) underlying this phenomenon are not established. It is known that ATP depletion disrupts actin microfilaments [56, 71] by fostering the conversion of monomeric (G) actin to F-actin [56, 99]. As noted above, proper functioning of the actin-based cytoskeleton is essential for the maintenance of normal epithelial permeability characteristics. The tendency for actin to polymerise under conditions of ATP depletion (27, 28, 34) is paradoxical, since *in vitro*, the polymerization of G-actin to F-actin is an energy-requiring event, which depends upon the irreversible hydrolysis of ATP (35). Only tiny quantities of G-actin are required for filament growth *in vitro*, thus, at equilibrium, the majority of actin *in vitro* is present in its polymerized form (36). *In vivo*, however, approximately half of the actin in cells is present in its monomeric form (36). No adequate explanation has been advanced to explain this paradox, but we hypothesize that ATP depletion may foster cytoskeletal derangements by interfering with normal intracellular calcium homeostasis.

NITRIC OXIDE

Produced by mammalian cells from the amino acid, L-arginine, the small molecule, nitric oxide (NO·), has been identified as an important regulator and/or effector of many phenomena in the cardiovascular, nervous, and immune systems [106]. Increasingly, it is apparent that NO· also plays a versatile role in the physiology and pathophysiology of the gastrointestinal tract [137].

The reaction responsible for the formation of NO· is catalysed by a family of enzymes called nitric oxide synthase (NOS) [68, 90]. There are three isoforms of this enzyme, including: neuronal or type I NOS found primarily in neuronal tissues and skeletal muscle; endothelial or type III NOS (eNOS), found primarily in endothelial cells; and inducible or type II NOS found in a wide variety of cell types, including macrophages and hepatocytes. Both nNOS and eNOS are constitutively expressed, and the production of NO· by these enzymes is dependent on the presence of calmodulin and intracellular concentrations of Ca^{2+}. In contrast, iNOS contains calmodulin as a tightly bound subunit even under nominally Ca^{2+}-free conditions, and the enzyme is expressed only after induction by various cytokines or LPS.

A large variety of cell types in the gut are potential sources of NO·. These cell types include myenteric neurons [16, 78, 107, 156], vascular endothelial cells [107, 117] and interstitial cells of Cajal [118]. Inflammatory cells in the submucosa, including mast cells [58], macrophages [43, 139], and polymorphonuclear leucocytes [47, 85], are capable of producing NO·. Luminal bacteria represent another potential source of NO· in the gastrointestinal tract [41].

Enterocytes also appear to be capable of producing NO·, at least under certain conditions. Boughton-Smith and colleagues reported that iNOS activity is elevated in biopsy specimens of inflamed colonic mucosa from patients with ulcerative colitis [10]. These investigators have also documented that administration of LPS to rats leads to the induction of iNOS activity in homogenates of jejunal or colonic tissue [11]. These results suggest that various inflammatory states (e.g. ulcerative colitis and acute endotoxicosis) are associated with induction of iNOS activity in gut epithelial cells, although the observed data also could be explained by iNOS induction in resident or infiltrating inflammatory cells in the mucosa or lamina propria. Tepperman and colleagues, however, have documented upregulation of iNOS activity in isolated enterocytes harvested from the colons of rats injected 4 h earlier with LPS [142]. Furthermore, these workers have shown that prior administration of an anti-neutrophil antiserum prevents LPS-induced leucosequestration in the colonic mucosa, but has no effect on measured concentrations of iNOS activity, supporting the view that infiltrating neutrophils are not the source of the iNOS activity in enterocytic preparations from endotoxic rats.

The idea that enterocytes can be induced to produce NO· is further supported by preliminary findings obtained by several laboratories. For example, Grisham has demonstrated that exposure of cultured IEC-18 (rat intestinal epithelial) cells to LPS, IL-1, or TNF-α plus IFN-γ, increases production of nitrite plus nitrate (markers of NO· production) [46]. Dignass, Podolsky and Rachmilewitz showed that incubation of cultures of another rat enterocytic cell line (IEC-6) with a number of different cytokines (e.g. IL-2, TNF-α) results in modest increases in the production of nitrogen oxides [33]. Recently, our group has shown that incubation of Caco-2_{BBe} cells with the pro-inflammatory cytokine, IFN-γ, increases the release of markers of increased NO· production (nitrite and nitrate anions) into the media [147]. Even more recently, we have shown that incubation of Caco-2_{BBe} cells with INF-γ upregulates expression of iNOS mRNA [unpublished observations].

NO· appears to be capable of modulating intestinal epithelial permeability. Interestingly, depending upon the experimental system employed, NO· can either diminish or increase intestinal permeability to various water-soluble molecules. The idea that NO· plays a beneficial role to preserve normal gut barrier function is supported by a number of observations. In 1992, Kubes reported that infusion of a NOS inhibitor, N^G-nitro-L-arginine methyl ester (L-NAME), into the mesenteric artery of cats markedly increases ileal epithelial permeability to a hydrophilic probe [72]. In a subsequent study, Payne and Kubes documented that infusion of an NO· donor, such as sodium nitroprusside (SNP) or exogenous arginine (NOS substrate) ameliorates gut mucosal hyperpermeability induced by ischaemia/reperfusion [114]. Using a similar design, Boughton-Smith and colleagues showed that infusion of an NO· donor compound can ameliorate gut mucosal damage induced by intravenous injection of LPS in rats [12]. Conversely, treatment with NOS inhibitors has been shown to exacerbate gut epithelial hyperpermeability induced by ischaemia/reperfusion [73] and macroscopic mucosal damage induced by LPS [63]. Therefore, data from a number of *in vivo* studies support the following conclusions: (1) under basal conditions, endogenous production of NO· serves to maintain normal permeability of the intestinal mucosa; (2) under basal conditions, blocking NO· synthesis increases gut mucosal permeability; (3) in certain pathological conditions associated with derangements in gut mucosal barrier function and/or integrity (e.g. ischaemia/reperfusion injury or endotoxicosis), provision of exogenous NO· tends to maintain normal intestinal epithelial structure and function; (4) in these same pathological conditions, blockade of NO· biosynthesis tends to exacerbate derangements in the structural and functional integrity of the mucosa.

In contrast with these findings are other data which suggest that overproduction of NO· can be deleterious to the integrity of the intestinal mucosal barrier. For example, Lopez-Belmonte, Whittle and Moncada showed that close arterial infusion of NO donors, SNP or *S*-nitroso-*N*-acetylpenicillamine (SNAP), causes gastric mucosal damage in the rat when infused at high concentrations [79]. Similarly, Tepperman and colleagues reported that NO· donors, such as SNP or SNAP, decrease the *ex vivo* viability of freshly harvested rat colonic epithelial cells [142]. Tepperman and colleagues also showed that *in vivo* administration of LPS decreases the viability of gut epithelial cells via an NO·-dependent mechanism [142, 143]. Recently, our group demonstrated that NO· donors (SNP or SNAP) as well as authentic NO· gas are capable of increasing the permeability of Caco-2_{BBe} monolayers to a variety of hydrophilic macromolecules [129]. The deleterious effect of NO· on barrier function appears to be mediated through derangements in intracellular ATP production and cytoskeletal organization [129].

CYTOKINES

Recent studies performed using cultured T_{84} enterocytic cells suggest that certain proinflammatory cytokines, namely IFN-γ and IL-4, are capable of increasing the permeability of model epithelia [1, 24, 84]. The mechanism(s) whereby cytokines, such as IFN-γ, induce intestinal epithelial hyperpermeability have not been determined. It is known, however, that IFN-γ, acting either alone or in combination with other cytokines, is capable of triggering increased production of NO· by a number of different cell types [69, 89, 154, 162]. Thus, it seems plausible that cytokine-induced intestinal epithelial hyperpermeability is mediated through induction iNOS leading excess NO· production. In support of this view are recent data published by our group, showing that: (1) incubation of Caco-2_{BBe} (enterocytic) cells with IFN-γ increases the release of NO· oxidation products (nitrite and nitrate) into culture supernatants; (2) Caco-2_{BBe} monolayers can be rendered hyperpermeable by incubation in media containing IFN-γ; and (3) coincubation of Caco-2_{BBe} monolayers with INF-γ and various NOS inhibitors significantly blunts the development of hyperpermeability [147].

Conclusions

Although attractive on theoretical grounds, the notion that gut barrier dysfunction contributes to morbidity, including MODS, in critically ill patients remains unproved. Despite the presence of negative data, however, this concept remains a fruitful line of investigation both at the bedside and in the laboratory. At the very least, learning about the mechanisms underlying gut barrier failure in critical illness will provide insights into the mechanisms of cellular dysfunction of all kinds associated with sepsis or other causes of diffuse inflammation. At best, this avenue of investigation will lead to improvements in management and a reduction in morbidity and mortality in victims of trauma, sepsis or other acute life-threatening illnesses.

Mechanisms of acute renal failure

C. J. LOTE, L. HARPER AND C. O. S. SAVAGE

Acute renal failure can be defined as an abrupt decline in renal function with a decrease in glomerular filtration rate (GFR) resulting in the retention of nitrogenous waste products. Acute renal failure has conventionally been classified as (a) prerenal failure, denoting a disorder in the systemic circulation that causes renal hypoperfusion. Implicit in the prerenal classification is that the correction of the underlying circulatory disturbance (e.g. by improvement in cardiac function or repletion of volume) restores the GFR. However, prerenal failure is often followed by transition to (b) intrinsic renal failure, where correction of the circulatory impairment does not restore the normal GFR. Intrinsic renal failure generally includes tubular necrosis. (c) Postrenal failure (obstructive) is a third possibility.

Some patients with acute renal failure have oliguria (conventionally defined as a urine output of less than 400 ml day^{-1}), but others do not. In fact, patients with acute renal failure can be divided approximately equally into oliguric and non-oliguric. The pathogenetic factors appear to be identical in both types but in general are less severe in non-oliguric acute renal failure.

Three abnormalities of renal function are present in intrinsic acute renal failure. These are (1) intratubular obstruction, (2) backleak of glomerular filtrate through damaged tubular epithelium, and (3) a primary reduction of GFR as a consequence of the release of vasoactive substances, which alter pressure, flow and filtration coefficient (k_f) in the glomerular capillaries.

The kidneys have an enormous blood supply. They receive 20–25 % of the cardiac output, but account for only 0.5 % of the body weight. The renal blood supply is typically around 400 ml 100 g^{-1} min^{-1} compared with about 70 ml 100 g^{-1} min^{-1} for heart and liver. The kidneys also have a very high oxygen consumption, but because of the high blood flow, the arteriovenous oxygen difference across the kidney is small. $P\text{O}_2$ decreases from 95 mm Hg in the renal artery, to a value of about 70 mm Hg in the renal venous blood. In view of this it may seem surprising that renal ischaemia and acute renal failure are such major problems.

In this article we examine those features of the renal physiology which contribute to the (intrinsic) failure of the kidney after renal hypoperfusion. What happens when the renal circulation is compromised, and how does this lead on to intrinsic renal failure? How can an organ which has a huge blood supply, and a very low oxygen extraction, be so susceptible to ischaemia and hypoxia? The answers are complex; they necessitate an understanding of renal haemodynamics and their control, and of the role of the kidney in circumstances in which the effective circulating volume is reduced.

Renal blood supply

One of the first aspects of renal haemodynamics which physiology students learn is the concept of "autoregulation" (fig. 1). When mean renal arterial pressure is varied over the range 90–200 mm Hg, there is little effect on renal blood flow. The mechanism of this is still controversial; the most likely explanation is that there is a myogenic response, whereby the increased wall tension in the afferent arterioles, brought about by an increase in perfusion pressure, causes automatic contraction of the smooth muscle fibres in the vessel wall, thereby increasing the resistance to flow and so keeping the flow constant in spite of the increase in perfusion pressure. The alternative hypothesis is that a tubulo-glomerular feedback (TGF) mechanism is responsible for autoregulation, whereby increased perfusion pressure will increase filtration, increasing the tubular fluid delivery to the macula densa which then releases a factor or factors which causes vasconstriction. Which of these hypotheses is correct is debatable [33].

However, the concept of autoregulation can be very misleading. Notwithstanding autoregulation, when effective circulating volume decreases there is a reduction in renal blood flow. This should not be surprising. It has been known for a very long time that stimulation of the renal nerves causes loss of colour from the kidney surface as a result of renal vasoconstriction [4], and this renal vasoconstriction occurs at relatively low levels of renal nerve activity (2 Hz), with increases in both afferent and efferent arteriolar resistance. Higher levels of stimulation (5–20 Hz) primarily constrict the afferent arterioles [18].

(*Br. J. Anaesth.* 1996; **77**: 82–89)

Key words

Kidney, failure. Kidney, blood flow. Kidney, metabolism.

C. J. LOTE, BSC, PHD, (Physiology Department); L. HARPER, MRCP, C. O. S. SAVAGE, PHD, FRCP, (Department of Medicine); Nephrology and CCRIS, University of Birmingham B15 2TT. Correspondence to C. J. L.

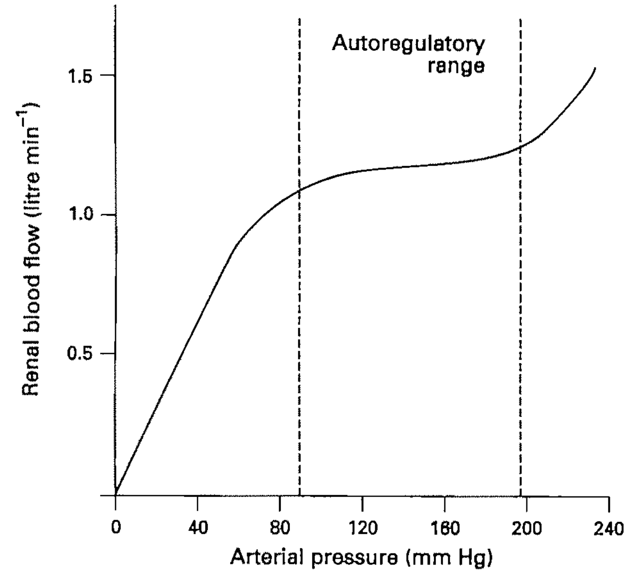

Figure 1 The autoregulation of renal blood flow. In the "autoregulatory range" (90–200 mm Hg), a change in the mean renal perfusion pressure has little effect on the blood flow. The graph can be misleading, since *in vivo* the kidneys do not respond passively to changes in blood pressure, but are active components of blood pressure regulation. (From ref. [22].)

As mentioned above, the kidneys, relative to their size, receive a huge fraction of the cardiac output (20–25 %), and in times of stress, sympathetically mediated renal vasconstriction can shunt the large blood flow to extrarenal sites. Thus, whereas the autoregulation diagram gives the impression that the kidneys *react* to changes in blood pressure, the reality is that the kidneys play a major role in the *regulation* of blood pressure, and many authors have emphasized that renal blood flow decreases whenever cardiac output is decreased secondary to volume depletion [24], although there is continuing controversy over the magnitude of the decrease.

Thus systemic blood pressure is not a good guide to the adequacy of renal perfusion. If there is a decrease in the effective circulating volume (for whatever reason), there may be catastrophic underperfusion of the kidneys, even though blood pressure is in the "autoregulatory" range; this is by virtue of the fact that it may be intense renal vasoconstriction that is the reason for the blood pressure being maintained. So, overt hypotension is not a prerequisite for the development of acute renal failure, and modest reductions in cardiac output, with maintained blood pressure, can imply substantial renal ischaemia. But, if the kidneys normally have such a large blood supply, why does ischaemic damage occur so readily?

The renal medullary blood supply

The function of the renal medulla is to maintain a high osmolality (produced by solute transport out of the ascending limb of the loop of Henle), in order to allow the tubular fluid to be concentrated by the osmotic abstraction of water from the collecting ducts. This function demands a specialized blood supply; conventional capillaries traversing the renal medulla would instantaneously dissipate the corticomedullary solute gradient. The specialization is the countercurrent arrangement of the vasa recta (fig. 2), which minimizes washout of solutes from the medullary interstitium. However, for vasa recta countercurrent exchange to operate, it is essential that the haematocrit of the blood entering the vasa recta should be low. If it were not, then the osmotic removal of water from the descending vasa recta (fig. 3) would dramatically increase the blood viscosity. Even with a low haematocrit, there is a considerable increase in viscosity due to the increase in intravascular protein concentration brought about by the countercurrent exchange of water. Furthermore, since the blood entering the descending vasa recta is derived from efferent arterioles and is unlikely to have gained any tubular fluid reabsorbate, the

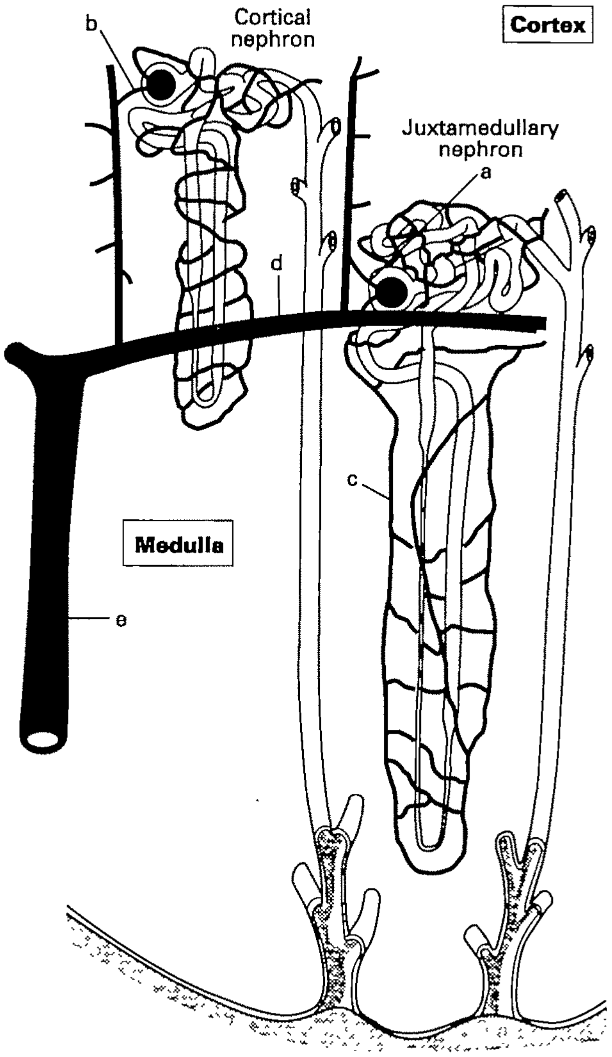

Figure 2 Diagram to show the anatomical arrangement of the blood supply to the nephrons. For clarity, venules and veins are omitted. A typical juxtamedullary nephron (15 % of the total) and cortical nephron (85 % of the total) are shown on the right and left respectively. Note that the afferent arterioles of the juxtamedullary nephrons (labelled a) leave the interlobular artery at a retrograde angle, whereas the afferent arteriole of the cortical nephron (labelled b) leaves at a shallow angle. Thus, plasma skimming is more likely in the blood to the juxtamedullary nephron, the efferent arteriole of which supplies the vasa recta (c). Only two nephrons are shown complete. Other afferent arterioles are shown, but not the glomeruli. Other labels: arcuate artery (d) running along corticomedullary boundary. Interlobar artery (e).

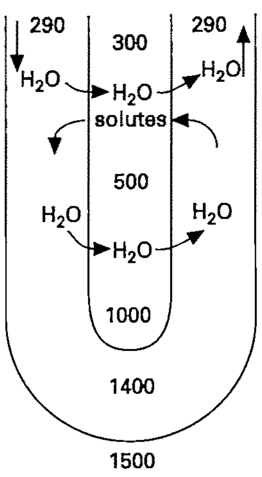

Figure 3 Countercurrent exchange of water and solutes in the vasa recta. The osmotic gradient in the renal medulla/papilla, set up by extrusion of sodium and chloride from the thick ascending limb of the loop of Henle (not shown), causes solute to enter the descending vasa recta limb (on left), and water to leave, so that there is equilibration with any level of the interstitium. The removal of water from the descending limb raises the plasma protein concentration and concentrates the erythrocytes. Hence a low haemocrit at the beginning of the vasa recta is necessary. (From ref. [22].)

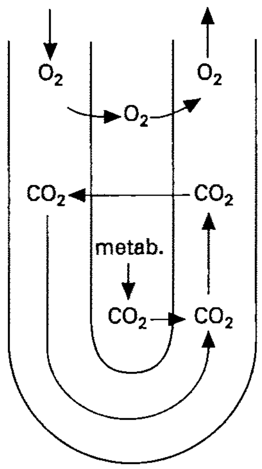

Figure 4 Countercurrent exchange of oxygen and carbon dioxide in the vasa recta. The diffusion gradient causes oxygen to leave the descending limb and enter the ascending limb, and vice versa for carbon dioxide. Thus the cells deep in the renal medulla/papilla have a hypoxic and hypercapnic environment. (From ref. [22].)

increased viscosity which will have occurred because of glomerular filtration will still be present in the blood entering the vasa recta.

Most measurements of the haematocrit for the blood entering the inner medullary descending vasa recta give values of about 10% [31]. Why is the haematocrit low in the blood entering the vasa recta? The vasa recta are derived from the efferent arterioles of juxtamedullary nephrons, which are the first nephrons to be supplied by the interlobular arteries (fig. 2). There are some obvious differences between the afferent arterioles of juxtamedullary glomeruli when compared with other glomeruli. The afferent arterioles of the juxtamedullary glomeruli, as they branch from the interlobular arteries, do so at right angles or even at retrograde angles [21]. This leads to plasma skimming [2] so the blood which enters the branch vessel (the afferent arteriole) is likely to have a reduced haematocrit. The important point is that the volume of the blood flow into the medulla is not a good indication of the adequacy of the blood supply for tissue metabolism, because of the low haematocrit and hence low oxygen-carrying capacity of the blood. This situation is then further exacerbated by the countercurrent exchange process in the vasa recta, because oxygen and carbon dioxide take part in this countercurrent exchange (fig. 4) [22]. Consequently, the cells of the renal papilla live in a remarkably hostile environment, with high (and labile) osmolality, poor oxygen delivery, and poor carbon dioxide removal. The degree of hypoxia in this part of the kidney is shown in figure 5.

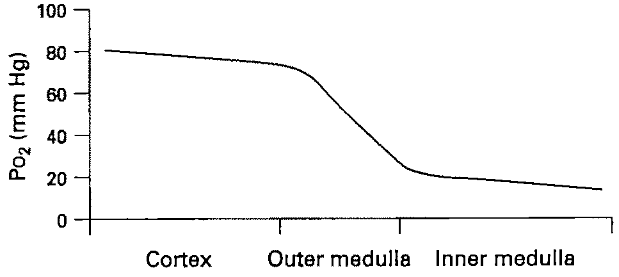

Figure 5 The Po_2 (mm Hg) from cortex to medulla, showing the dramatic decreases in Po_2 in the inner medulla as a result of countercurrent exchange of oxygen in vasa recta (as shown in fig. 4).

Thus, although the blood flow rates in the renal medulla and papilla are well within the range found in other metabolically active tissues, the low haematocrit and countercurrent exchange of oxygen lead to very low oxygen availability for the papillary cells.

The renal cortical blood supply

The obvious specialization of the cortical blood supply is the fact that there are two capillary beds in series—the glomerular capillaries and the peritubular capillaries. These are linked by the efferent arterioles which thus constitute portal vessels. There are a number of reports that the Pco_2 is high in the renal cortex (e.g. ref. [9]) and it is suggested that this is because countercurrent exchange can occur in the cortical peritubular capillaries, as it does in medullary vasa recta. However, others have found typical tissue values of Pco_2 in the renal cortex [25], and at the time of writing the question of whether renal cortical tissue Pco_2 is atypically high remains unresolved.

The kidneys as guardians of the effective circulating volume

Renal tissue damage will occur when the renal blood supply is insufficient to sustain the metabolic demands of the cells. Hypoxia limits ATP production, and hence impairs those cells dependent on oxidative metabolism [35]. Changes of cellular pH as a consequence of oxygen deprivation can also impair glycolytic (anaerobic) metabolism [27].

Although it might be supposed that the renal sites which have the highest oxidative metabolism (i.e. proximal tubule), would be the ones most affected by

hypoxia, the structural factors considered earlier also have a major bearing. The proximal convoluted tubules have the highest Na^+-K^+-ATPase activity. However, the S3 segment (pars recta—the part of the proximal tubule which descends into the medulla), and the medullary thick ascending limb of Henle (both of which have considerable glycolytic capability) are the sites commonly damaged in ischaemic acute renal failure. These sites, while having important transport roles, are also affected by the oxygen shunting in the vasa recta.

Eighty percent of the renal oxygen consumption is utilized to drive the Na^+-K^+-ATPase on the basal side of the tubule cells which is responsible for nephron sodium reabsorption. Many of the other transport processes along the nephron (e.g. glucose reabsorption, amino acid reabsorption, organic acid secretion) are secondary active processes which are driven by the gradient for sodium entry across the apical membrane. Thus, there would be almost no transport across the tubular cells without Na^+-K^+-ATPase activity. However, there are differences in the properties of the Na^+-K^+-ATPase in different nephron segments. For example, the Na^+-K^+-ATPase is 10–30 times more sensitive to ouabain in the collecting tubule (where the final adjustments to sodium excretion occur) than in the proximal tubule [8]. These differences raise the possibility of different control mechanisms over Na^+-K^+-ATPase activity in different nephron segments. This is discussed in more detail below.

As the foregoing has demonstrated, decreases in effective circulating volume lead to a reduction in renal perfusion, and this threatens the kidneys by further reducing the blood supply to sites where it is only just adequate. However, renal hypoperfusion is a signal of hypovolaemia to the kidneys, and brings into play renal correcting mechanisms to increase sodium and water reabsorption, and hence restore effective circulating volume. But for the kidneys to do this, their oxygen consumption must increase. This sequence of events, potentially leading to renal failure, is shown in figure 6.

Renal hypoperfusion is a powerful stimulus to renin release from the renin-containing granular cells of the afferent arteriole. Three main signals mediate this release.

(1) *The afferent arteriolar "baroreceptor" mechanism.* Decreased wall tension in the afferent arterioles as a consequence of decreased renal perfusion, increases renin release.

(2) *The sympathetic innervation to the granular cells.* Systemic baroreceptor reflexes activated by decreased effective circulating volume (and consequent decreased blood pressure) increase the activity in these nerves, increasing renin release.

(3) *The macula densa.* This is a sensor in the early part of the distal tubule (which is in close proximity to the afferent arteriole), which responds to decreased sodium chloride delivery into the distal tubule by increasing renin release. Sodium chloride delivery to this site decreases when there is a decrease in effective circulating volume, as a consequence of several factors, including decreased GFR, and decreased peritubular capillary hydrostatic pressure which leads to increased proximal tubular reabsorption.

The consequences of increased renin release are shown in figure 7 where it can be seen that the effects of increased angiotensin II production serve to increase effective circulating volume. Incidentally, the renal vasoconstriction induced by angiotensin II is predominantly of the efferent arteriole, but the renal vasoconstrictor effect of angiotensin II is anyway markedly attenuated because angiotensin II is a powerful stimulus for the production of vasodilator prostaglandins (see blow). Thus, the vasoconstrictor effect of angiotensin II is primarily, (though not exclusively) systemic rather than renal.

However, another vasoconstrictor peptide, endothelin-1 may act more locally. Its release and the tissue sensitivity to its effects are both enhanced by hypoxia [17]. Endothelin-1 mediates afferent and efferent arteriolar vasoconstriction, reducing renal plasma flow and glomerular filtration rate (fig. 6).

The sequence of events shown in figure 6 might seem to indicate that renal failure would be inevitable whenever there is a decrease in effective circulating volume, and this is obviously not the case. This is because there are intrinsic renal protective mechanisms. To a large extent, these are dependent on arachidonic acid metabolism.

Protective role of renal arachidonic acid metabolism

There are many excellent recent reviews of renal arachidonic acid metabolism [23]. This section will therefore focus on those aspects of arachidonate metabolism which have particular relevance to renal function in hypoxia and ischaemia.

The availability of free arachidonic acid as a substrate for the enzymes which convert it to active products, is very limited, since most of the esterified arachidonic acid which is converted to free arachidonic acid by phospholipase A2 is normally re-esterified. This requires ATP, and hence is oxygen dependent, so hypoxia and ischaemia are powerful stimuli for renal prostaglandin synthesis. An alternative or additional possibility is that a hypoxia-induced increase in intracellular (cytosolic) Ca^{2+} concentration enhances phospholipase A2 activity [23].

Free arachidonic acid can be metabolized via three routes, as shown in figure 8. The major cyclo-oxygenase products have renal tubular and renal vascular actions, both of which are important in the renal response to ischaemia and anoxia. Non-steroidal anti-inflammatory drugs (such as indomethacin) which are cyclo-oxygenase inhibitors, have little or no effect on renal blood flow (RBF) or GFR in healthy subjects, but cause marked decreases in RBF and GFR when the renal circulation is compromised, for example by haemorrhage [6]. This indicates that vasodilator products of the cyclo-oxygenase enzyme (mainly prostaglandin E_2 and prostacyclin PGI_2) play an important role in maintaining blood flow and GFR in these circumstances.

In addition to these haemodynamic vasodilator actions, PGE_2 also reduces sodium reabsorption in the thick ascending limb of the loop of Henle [32] and the collecting duct [19] and hence reduces the oxygen consumption of the cells at these sites [20].

Figure 9 The renal protective effects of arachidonic acid metabolism.

Products of the cytochrome P450-dependent mono-oxygenase enzyme may also be important in the ischaemic kidney. One product of this enzyme, probably a derivative of 11, 12-dihydroxyeicosatrienoic acid, produced in cells of the thick ascending limb of Henle, is a sodium potassium ATPase inhibitor at this site, and another (5,6-eicosaepoxytrienoic acid) is a vasodilator [5].

The renal protective actions of the arachidonic acid products are summarized in figure 9.

Other protective mechanisms

It was mentioned earlier that there are differences in the control over Na^+-K^+-ATPase activity at different sites in the nephron, and this fact will have been apparent from the foregoing section. However, arachidonic acid products are not the only humoral agents which influence Na^+-K^+-ATPase activity. The effects of aldosterone are predominantly on the activity of Na^+-K^+-ATPase in the collecting tubule, where it acts by inducing the synthesis of new transporter molecules [12]. However this, of course, increases oxygen demand. There are other agents which reduce oxygen demand, important among which are atrial natriuretic peptide and its renal analogue, renal natriuretic peptide (urodilatin) [14, 36] (fig. 10). There are high affinity binding sites for these peptides in the collecting ducts, binding to which leads to an increase in intracellular cGMP, which in turn inhibits ouabain-sensitive oxygen consumption [36] and this is assumed to inhibit sodium transport.

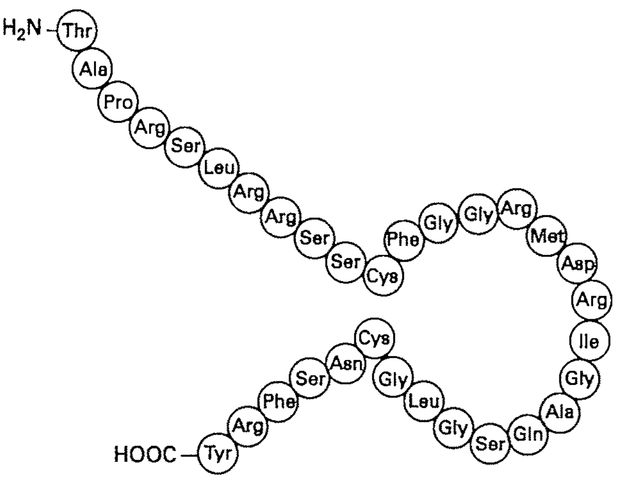

Figure 10 Renal natriuretic peptide (urodilatin). The major circulating form of atrial natriuretic peptide, α-human ANP, is identical except that it does not contain the 4 N-terminal amino acids (Thr, Ala, Pro, Arg).

Recent evidence suggests that atrial natriuretic peptide is primarily a cardiovascular regulator and relatively unimportant for sodium excretion, whereas renal natriuretic peptide is more likely to participate in the intrarenal regulation of sodium excretion [13]. The renal natriuretic peptide is synthesized in the distal cortical nephron, and may be secreted into the cortical peritubular capillaries, or directly into the tubular lumen [36].

Role of endotoxins, inflammatory mediators and nitric oxide in acute renal failure

Sepsis is a common cause of acute renal failure and septicaemia is a common event in patients with acute renal failure, particularly those requiring intensive care. Infective agents may exert their effects by both direct and indirect mechanisms. Many of the indirect effects are mediated through the potent bacterial product, endotoxin or lipopolysaccharide (LPS). LPS may act on many cell types, particularly endothelial cells, monocytes and neutrophils. It can bind directly to, and activate cells via the glycosylphosphoinositol-anchored membrane protein CD14; interactions between LPS and CD14 are facilitated by serum factors including LPS binding protein.

The endothelial cell phenotypic changes induced by LPS are almost identical to those induced by the cytokines TNF and IL-1 [7, 28] and include: (a) the upregulation of cell surface adhesion molecules such as E-selectin, ICAM-1 and VCAM-1 that promote leucocyte adhesion and transmigration; (b) the development of a procoagulant surface through enhanced expression of tissue factor, enhanced release of von Willebrand factor from internal stores in response to agonists (e.g. thrombin), increased secretion of plasminogen activator inhibitor-1 (with subsequent reduced fibrinolytic capacity) and reduced expression of thrombomodulin (with reduced activation of the protein C, protein S pathways); (c) the induction of inflammatory mediator secretion from endothelial cells, including prostacyclin (PGI_2) platelet activating factor (PAF), nitric oxide (NO) and endothelin-1; and (d) the secretion of growth factors, secondary cytokines, leucocyte chemoattractants and enzymes related to matrix degradation.

In addition to its effects on endothelial cells, endotoxin may also activate neutrophils and monocytes, while within the kidney it may induce adhesion molecule upregulation on renal epithelial and mesangial cells. Injection of endotoxin into baboons caused acute renal failure and dramatic upregulation within glomeruli of the adhesion molecule E-selectin (that binds ligands on neutrophils, monocytes and some T-cells) [28]. Accumulated activated neutrophils secrete proteases and free oxygen radicals which damage the glomerular basement membrane and nearby cells. Activated monocytes express tissue factor (favouring coagulation) and secrete further cytokines including IL-1 and TNF that potentiate the effect of endotoxin.

Many of the secondary inflammatory mediators induced by endotoxin can have far reaching effects. Thus, PAF is a product of arachidonic acid metabolism that is released by vascular endothelial cells and which, among its many functions, is a potent platelet activator. The two vasodilators PGI_2 and NO may be released from endothelial cells in response to LPS, while LPS-stimulated monocytes and mesangial cells are a further source of NO [30]. The induction of NO by endotoxin in these cell types differs, reflecting the predominant NO synthase (NOS) enzyme present; NOS generate NO from the terminal guanidino nitrogen of L-arginine. Endothelial NOS is a constitutive enzyme that is dependent on calcium and calmodulin for activity and it continuously produces nmol quantities of NO. Macrophage NOS is not calcium/calmodulin dependent and is induced by endotoxin and certain cytokines such as TNF and IL-1; this induction occurs over hours as it requires new protein synthesis but it leads to sustained production of mmol quantities of NO. Endotoxin and cytokine upregulation of NO from endothelial cells occurs because these factors increase the levels of tetrahydrobiopterin, an essential cofactor, although recently an inducible NOS has been described in endothelial cells also. An inducible NOS is present too in glomerular mesangial cells. NO inhibits platelet aggregation (as does PGI_2) and adhesion to collagen, effects which may be renal protective. However, excess NO levels in sepsis are blamed for the negative inotropic effects on cardiac muscle and for the profound vasodilatation (often resistant to vasopressors) that occurs in septic shock. Nitric oxide has complex interactions with other vasoactive systems—angiotensin II, sympathetic nervous system catecholamines, endothelin I, and prostaglandins; a detailed description of these effects is beyond the scope of this article but they are reviewed in ref. 30.

In parallel with the enhanced NO production, endotoxin may also upregulate the potent constrictor peptide, endothelin [17]. Local endothelin I production may contribute to the renal vasoconstriction that occurs during septic shock since administration of anti-endothelin immunoglobulin directly into the renal artery completely reverses endotoxin-induced renal vasoconstriction.

Prevention of acute renal failure

Prevention of acute renal failure is clearly a better option than treatment. Patients at risk of acute renal failure can be identified and certain simple measures may help to prevent the subsequent development of acute renal failure.

The following conditions predispose to development of acute renal failure:

(1) pre-existing renal impairment
(2) diabetes mellitus (both insulin-dependent and non-insulin dependent)
(3) hypertension and/or vascular disease, particularly renal vascular disease
(4) jaundice
(5) multiple myeloma
(6) age.

The incidence of acute renal failure in the above groups of patients is high after the use of i.v. contrast media, use of nephrotic drugs (e.g. non-steroidal anti-inflammatory drugs, gentamicin, amphotericin) and surgery. Measures that may be taken to reduce the risk of acute renal failure include discontinuation of nephrotoxic agents wherever possible (such as non-steroidal anti-inflammatory drugs) or monitoring levels carefully to avoid toxic concentrations (as with gentamicin).

It is important to eliminate dehydration in "at risk" individuals by evaluating fluid status (if necessary with a central venous catheter) and administering fluid (if necessary i.v. using normal saline in preference to 5% dextrose in patients with renal impairment). Adequate extracellular volume status before major surgery is an excellent preventative measure particularly in the jaundiced patient or those undergoing aortic surgery [3]. Recently, in a prospective study, patients with a mildly elevated creatinine who underwent coronary angiography were hydrated with 0.45% saline before and after angiography. Saline alone significantly reduced the risk of renal failure induced by radiocontrast agents compared with saline and frusemide or mannitol [34].

The role of dopamine as a renoprotective agent is controversial. Dopamine is used widely in the dose range 2–5 $\mu g\ kg^{-1}\ min^{-1}$ and is said to act as a renal vasodilator. There is significant overlap in the stimulation of beta-adrenergic and alpha-adrenergic receptors even at these doses. The increased blood flow is probably the result of the inotropic effects of dopamine and can be reproduced by other non-dopamineric inotropes. In a randomized double-blind trial [11], dopamine and dobutamine were compared for their ability to improve renal function. Dopamine acted as a diuretic and did not improve creatinine clearance. Dobutamine, a non-dopaminergic inotrope, improved creatinine clearance without a change in urine output [11].

The diuresis commonly seen after administration of dopamine is probably the result of a direct tubular effect. However, dopamine impairs the important tubuloglomerular feedback mechanism which may adversely affect the oxygen supply and demand balance, possibly promoting the development of acute tubular necrosis [10]. Dopamine is commonly used to prevent acute tubular necrosis. The evidence supporting this is poorly controlled and often anecdotal. A recent well designed trial [1] showed no benefit in the prevention of renal dysfunction in well hydrated patients undergoing elective abdominal surgery receiving dopamine [1]. In another controlled study, patients undergoing coronary artery bypass surgery failed to derive any benefit from prophylactic dopamine [26]. There is one study in which dopamine protected against radiocontrast-induced renal failure in patients with pre-existing renal impairment; however, no diabetics were included [16].

Mannitol is an osmotic diuretic which if administered prophylactically to patients undergoing surgery can reduce the incidence of acute renal failure. However a recent prospective trial found no additional benefit beyond adequate hydration [15]. The beneficial effects of mannitol are thought to be due to decreased intratubular obstruction and improved renal haemodynamics secondary to an increase in medullary blood flow and cellular protection.

At present there is no acknowledged treatment which reduces duration or mortality of acute renal failure since the advent of dialysis. However, recent animal studies have indicated that atrial natriuretic peptide (ANP) attenuates the severity and/or accelerates the recovery in experimental models of acute renal failure [29]. ANP increases GFR in pathological states, by increasing the glomerular capillary perfusion pressure and has a direct diuretic and natriuretic effect on the distal tubule as described earlier. In a randomized blinded study in humans, ANP appeared to reduce the need for dialysis and increased creatinine clearance when given parenterally to those patients with established intrinsic acute renal failure. There was no improvement in mortality [15]. This study needs to be reproduced in larger trials before definitive conclusions on the use of ANP in acute renal failure can be made.

Conclusions

The structural specialization of the renal circulation is necessary for its function, but some features of the specialization make the kidneys prone to ischaemic and/or hypoxic failure. Most importantly, despite the low oxygen extraction overall, the renal blood supply is not excessive, and indeed is barely adequate in some areas. Excessive reliance on blood pressure measurements (indicating a pressure in the "autoregulatory range") overlooks the fact that the renal blood flow is labile since the kidneys contribute to the regulation of blood pressure.

So, is there an easy way of assessing whether the kidneys are failing after an ischaemic episode? Urinary measurements are a useful indicator. If the effective circulating volume has been reduced the kidneys, if functioning normally, will be maximally reabsorbing sodium and water. Consequently, the urine volume will be small, urine osmolality will be high (e.g. over 800 mosmol/kg H_2O), and the urinary sodium concentration will be low (e.g. less than

25 mmol litre^{-1}). In contrast, if the deceased effective circulating volume has induced renal failure, then urine volume will be small (or there may be no urine produced at all) as a consequence of decreased GFR; but if any urine is produced, it is likely that the urine osmolality will be close to the plasma osmolality (300 mosmol kg^{-1} H_2O) and the urinary sodium will be around 140 mmol litre^{-1}. This is because in acute renal failure, renal concentrating ability is lost. However, there can be considerable overlap between urinary values in prerenal and intrinsic renal failure, and although it is true that most oliguric patients with urine osmolalites below 350 mosmol kg^{-1} H_2O will have intrinsic renal failure, and most with osmolalities over 500 will have prerenal failure, values in between can occur in both conditions.

Fulminant and late onset hepatic failure

A. E. S. GIMSON

For many years the definition of fulminant hepatic failure, first introduced by Trey and Davidson in 1970, has been used, describing a clinical syndrome of sudden massive hepatocyte dysfunction in the absence of prior liver disease and resulting in hepatic encephalopathy [93]. Although in many series mortality has continued to reach 80%, those that do survive have full functional and structural regeneration without the development of chronic liver disease.

In recent years there has been a renewed debate as to the definition of fulminant hepatic failure [12, 72]. Previous groups have restricted the diagnosis to those with encephalopathy developing between 3, 4 or 6 weeks [7, 9, 33, 41]. The King's College Group has recently proposed a new terminology around the core term acute liver failure. Those patients presenting within 7 days of the onset of jaundice were defined as having hyperacute liver failure, those presenting within 8–28 days of jaundice defined as acute liver failure and those presenting between 29 and 72 days as having subacute liver failure. This definition is of importance as it categorizes groups with different aetiologies and, more importantly, different incidence of the major complication cerebral oedema. This is more common in those with hyperacute or acute liver failure and less common in those with the subacute variety. Similarly, there are differences in prognosis. In hyperacute liver failure with medical management alone the prognosis is relatively good (36% survival) where as in those with subacute liver failure prognosis is poor with only a 14% survival rate. All these studies have concluded that duration from onset of symptoms to encephalopathy is of prime importance in defining different prognostic groups, irrespective of the aetiology, and exemplify the fact that fulminant hepatic failure represents a heterogeneous group of conditions with diverse aetiologies and prognoses. Assessing the aetiology is, therefore, of crucial importance not only because of specific therapy directed to that aetiology but also in predicting subsequent outcome and need for additional nonmedical interventions such as orthotopic liver transplantation.

Aetiology

Fulminant hepatic failure is uncommon and the majority of cases are the result of drug hepatotoxicity or viral hepatitis (table 1).

DRUG HEPATOTOXICITY

Paracetamol hepatotoxicity, the most common cause of fulminant hepatic failure in the United Kingdom, usually occurs after consumption of more than 12 g of the drug. More recently the importance of inadvertent paracetamol hepatotoxicity often taken for an intercurrent illness and without suicidal intent has been stressed. Patients with enzyme induction due to alcohol abuse [61] or the consumption of enzyme-inducing drugs leads to induction of the cytochrome system and increased production of the toxic metabolite [57]. Hepatic metabolism of paracetamol initially occurs via sulphation and glucuronidation. When this metabolic pathway is saturated a cytochrome P450 mechanism may result in the formation of an unstable toxic nucleophilic compound *N*-acetyl-*p*-benzoquinone imine. This compound is detoxified by tissue glutathione and when stores of this are depleted hepatic damage occurs. Prior depletion of tissue glutathione due to oxidant stress or alcohol consumption will also aggravate hepatocyte injury. The antidote *N*-acetylcysteine (NAC) if given within 16 h of the overdose may act as a sulphydryl donor and neutralize the toxic metabolite. Recent evidence from retrospective analyses [47] as well as a prospective randomized controlled trial suggest that patients with significant hepatotoxicity and liver failure may benefit from NAC even when given more than 16 h after the initial overdose. In these important studies reduced organ dysfunction and significantly improved survival were observed [56]. While the mechanism of action of NAC at this later stage is likely to be different from that when given within the first 16 h it is clear that all patients who have taken a significant paracetamol overdose and have evidence of hepatotoxicity should be given a continuous NAC infusion until normalization of markers of hepatocyte damage.

A wide range of other drug toxicities may occur leading to fulminant hepatic failure. Halothane hepatotoxicity is now rare, usually occurring in

Table 1 Aetiology of fulminant hepatic failure

Viral
  Acute hepatitis A (HAV)
  Acute hepatitis B (HBV) ± hepatitis D co-infection
  Hepatitis D (HDV) superinfection of a chronic HBV carrier
  Hepatitis B reactivation in a chronic HBV carrier
  Acute hepatitis C (HCV) ± other chronic viral carriage
  Acute hepatitis E (HEV)
  Indeterminate viral hepatitis
  Epstein-Barr virus infection, cytomegalovirus, herpes simplex, herpesvirus-6, varicella
Drugs
  Paracetamol (intentional/unintentional; with/without enzyme induction)
  Halothane, isoflurane, enflurane
  Carbon tetrachloride
  Rare idiosyncratic drug reactions: isoniazid, rifampicin, sodium valproate, ketoconazole, erythromycin, sulphonamides, tricyclic antidepressants, propyl thiouracil, FIAU
Others
  Acute fatty liver of pregnancy, pre-eclamptic syndromes
  Wilson's disease
  Autoimmune chronic active hepatitis
  Budd-Chiari syndrome
  Malignancy; non-Hodgkin's lymphoma, metastatic disease
  Heat stroke
  Amanita poisoning
  Circulatory shock
  Reye's syndrome
  Sepsis

females up to 21 days after exposure. Multiple exposures are common but it has been reported after a single anaesthetic. Occasionally there may be other features of drug hypersensitivity including a rash, eosinophilia and liver kidney microsomal antibodies in 25% of cases. A specific antibody against a halothane altered component of hepatocyte membranes suggests that the damage may be immunologically mediated. Hepatotoxicity has been reported on rare occasions following enflurane [104] and isofluorane as well as phenytoin, tricyclic antidepressant drugs and sodium valproate [23]. Recently, the importance of significant hepatotoxicity associated with anti-tuberculous medication has been stressed. In these patients oxidant stress and low tissue glutathione concentration as well as enzyme induction due to fasting or chronic alcohol abuse may also contribute to the likelihood of hepatic dysfunction [65].

VIRAL HEPATITIS

In most series fulminant viral hepatitis is the most common cause of acute liver failure. The reason for the development of liver failure in up to 1% of cases is unclear but presumably includes host factors such as age, as well as the size of the inoculum and perhaps virus strains. Fulminant hepatitis A (HAV) is more common in the elderly [36] and i.v. drug users [1] and the mechanism of the damage remains unclear. The prognosis is relatively good with survival rates of up to 50% with medical treatment alone. Fulminant hepatitis B (HBV) is an important cause of acute liver failure [40, 74], the risk of a fulminant presentation being higher than with HAV, and more common in women or after termination of chemotherapy and immunosuppression in HBV carriers [16]. It may also occur with HBV reactivation, with HBe antigen/HBe antibody seroconversion and when there is associated delta HDV co-infection or super-infection of HBV carriers [34, 44].

Table 2 Investigations in patients with fulminant hepatic failure

Full blood count
Prothrombin time/prothrombin ratio
Serum electrolytes, creatinine and phosphate
Serum bilirubin, albumin, transaminases, alkaline phosphatase, amylase
Serum/urine for toxicological screen
Viral serology
  HAV IgM anti-HAV
  HBV HBsAg, IgM anti-HBc, HBV DNA
  HCV Anti-HCV antibody, HCV mRNA
  HDV IgM anti-HDV
  HEV Anti-HEV antibody
  Serology for CMV, EBV, herpes, etc. and convalescent sera if available.
Serum copper, caeruloplasmin. 24-h urinary copper and penicillamine challenge if appropriate
Autoantibodies/immunoglobulins
Chest x-ray
Ultrasound scan of liver (size, texture, patency of portal/hepatic veins. Spleen size)
Slit-lamp examination for Keyser-Fleischer rings

Hepatitis C (HCV) has been considered only rarely as a cause of acute liver failure, on the basis on anti-HCV serology [43]. In contrast, recent studies have suggested that HCV may account for up to 30% of cases of serologically indeterminate viral hepatitis when HCV mRNA is tested by polymerase chain reaction (PCR). In these studies the importance of multiple viral co-infection has also been stressed. Other viral causes include hepatitis E infection [3, 60], particularly in the Indian subcontinent and rarely Epstein-Barr virus [26], cytomegalovirus [49], herpes simplex [24], varicella [66] and herpesvirus-6 [73]. These cases often occur in immunocompromised individuals.

A long list of rare causes of fulminant hepatic failure account for approximately 5% of the cases but accurate diagnosis is essential (table 2). Liver failure associated with pregnancy may be caused by acute fatty liver of pregnancy or eclamptic syndromes [27, 80, 81]. The Budd-Chiari syndrome [78], disseminated malignancy (in particular non-Hodgkin's lymphoma [102]) and Wilson's disease may also present a fulminant course [8]. The clue is often the presence of hepatosplenomegaly. Reye's syndrome is a further rare cause of acute liver failure but is more common in young children [31]. The cause is unknown but interest has centred on the role of salicylates and the use of these drugs in febrile children is no longer recommended. In such cases the primary lesion of diffuse microvascular fatty change within the liver is different from that observed in most other forms of fulminant hepatic failure. Liver failure has also been recorded in children treated with sodium valproate [103] or tetracycline hepatoxicity and Jamaican vomiting sickness. Recently the development of a diffuse microvascular infiltrate with hepatocellular necrosis has been observed following the use of nucleoside analogues and electron microscopic evidence has pointed to a primary mitochondrial damage [63].

Pathology

The majority of causes of fulminant hepatic failure give rise to a severe and widespread hepatocellular necrosis [52]. This starts in a centrizonal distribution and progresses towards the portal tracts [20]. The degree of associated parenchymal inflammation is highly variable, being more prominent in those with a longer duration of the disease [46]. Canalicular cholestasis may also be apparent but usually is the consequence of sepsis. Initial studies by Horney and Galambos suggested that pathogenesis of fulminant viral hepatitis was due to an ischaemic infarction [50] which, in the context of fulminant hepatitis B, was considered to result from sinusoidal deposition of antigen–antibody complexes following an exaggerated immune response to the hepatitis B virus [40].

Previous suggestions that fulminant hepatic failure may be associated with an impaired hepatic regenerative response have been discounted with the finding of prominent immunostaining for proliferating cell nuclear antigen in surviving hepatocytes [38] and elevated concentrations of hepatocyte growth factor [42].

General management

Management in an intensive care unit is mandatory. Patients require dextrose infusions, prophylaxis for upper gastrointestinal bleeding and close microbiological surveillance. Treatment of the coagulation deficit is needed only if there is overt bleeding.

Attempts at treating fulminant hepatic failure with steroids, insulin and glucagon have been unsuccessful. Other modalities tried have included PGE_1 [11, 88, 89] and interferon with cyclosporin A in patients with fulminant viral hepatitis [101]. These are either of no proved benefit or require further evaluation.

Organ dysfunction and treatment

HEPATIC ENCEPHALOPATHY AND CEREBRAL OEDEMA

During fulminant hepatic failure progressive encephalopathy is subsequently associated with the development of cerebral oedema. The clinical features range from minimal dysphoria and drowsiness in the initial stages to agitation and, later, unresponsiveness to all stimuli in grade 4 encephalopathy (table 3). The rate of progression through these grades varies significantly but is fastest with paracetamol-induced hepatotoxicity. Those patients with grade 4 encephalopathy who develop cerebral oedema have a very high mortality without treatment, compared with those who only develop grade 1 or 2 encephalopathy.

Table 3 Classification of grades of hepatic encephalopathy

Grade 1	Mild confusion, poor concentration occasionally dysphoria. Reversed sleep pattern. When roused fully coherent.
Grade 2	Increasing confusion and disorientation but still rousable and able to be rational.
Grade 3	Sleeping most of the time but can be roused to commands. May be markedly agitated occasionally aggressive.
Grade 4	Not rousable to commands but may or may not be responsive to painful stimuli. Clinical features of cerebral oedema may be apparent during this stage, including hyperventilation, pupillary abnormalities, opisthotonus and extensor plantars. Abnormal respiratory pattern.

The pathogenesis of hepatic encephalopathy in patients with acute liver failure remains unclear. The previous hypotheses centred around hyperammonaemia, changes in the proportional relationship between branch chain and aromatic amino acids, elevation of toxins such as mercaptans and short chain fatty acids with synergistic effects. Unfortunately these have not given consistent results in animal models and, more particularly, the visual evoked responses of animals exposed to these agents do not replicate the responses seen during liver failure. More recent evidence has pointed to the gamma amino butyric acid (GABA) pathway as the major cause of neuronal depression [67]. Although GABA concentrations are not elevated it has been postulated that benzodiazepine-like substances acting via a benzodiazepine receptor closely linked to the GABA receptor may be involved. Basile and colleagues have observed increased concentrations of 1,4-benzodiazepine in brain tissue in both animals and patients with acute liver failure [5, 6]. The relationship between these findings and changes in other neuroexcitatory and depressant pathways including serotinergic, dopaminergic and glutaminergic pathways, remains unclear. The use of a benzodiazepine receptor antagonist such as flumazenil has been associated with minor changes in coma grade for short periods of time but is of little clinical importance [45]. Opioidergic neurotransmission is also altered in animal models of liver failure with increased cerebral levels of Met-Leu encephalin.

Cerebral oedema remains one of the major causes of early mortality in fulminant hepatic failure. During grade 4 encephalopathy it may be present in up to 80 % of cases and is associated with an elevated intracranial pressure, reduction in cerebral blood flow (CBF) and cerebral metabolic rate for oxygen ($CMRo_2$). As intracranial pressure increases, critical impairment of cerebral oxygenation occurs, with the development of cerebral ischaemia, and tentorial herniation develops in about 25 % of cases. The pathogenesis of this cerebral oedema remains unclear and both cytotoxic and vasogenic hypotheses have been put forward. It is likely that both varieties of cerebral oedema share similar mechanisms at the endothelial level. Electron microscopic studies of brain from patients dying with fulminant hepatic failure have suggested a predominantly cytotoxic origin for the cerebral oedema [55]. This has been suggested to be the result of the presence of inhibitors of neuronal Na/K ATPase [87], although others have not confirmed these findings [75]. An alteration in the blood–brain barrier has also been observed in other animal models. It is most likely that these hypotheses are not mutually exclusive and that the increase in brain water content may initially be cytotoxic associated with glial swelling in cortical grey but not subcortical white matter, and subsequently be associated with alteration in the blood–brain barrier [54].

Cerebral oedema, as in many other pathological situations, is associated with changes in the normal cerebral blood flow autoregulation. Patients with grade 4 encephalopathy and fulminant hepatic failure have a low cerebral blood flow and do not exhibit the usual changes in cerebral blood flow with increases in Pa_{CO_2} [2]. This implies some uncoupling of the usual relationship between cerebral blood flow and $CMRo_2$ [59]. It is also clear that there are pronounced regional differences in cerebral blood flow.

The clinical detection of cerebral oedema is of critical importance [17, 62]. Reliance on such clinical features as systemic hypertension, bradycardia, opisthotonus, abnormal pupillary reflexes and decerebrate posturing only occur late and when therapeutic intervention may be ineffective. The use of computed tomography has variable sensitivity [68] but the most accurate assessment has been the use of an intracranial pressure monitor by the subdural route [18, 29, 62]. Complication rates are acceptably low and it allows the measurement of cerebral perfusion pressure, a critical measure of cerebral oxygen delivery. The increase in intracranial pressure to greater than 20 mm Hg, if untreated, is associated with the subsequent development of tentorial herniation. Transient increases in intracranial pressure may be associated with endotracheal suction, changes in patient position and painful stimuli. Management rests on maintaining normothermia, a head-up position of approximately 20° to the horizontal [25] and the use of i.v. mannitol 0.5 g/kg body weight. Previous trials have demonstrated that dexamethasone and hyperventilation [30] confer no survival benefit but mannitol when given for the above specific indication significantly improves hospital survival [21]. Both mannitol and NAC have been shown to increase cerebral blood flow in patients with grade 4 encephalopathy and this increase in cerebral blood flow is accompanied by an increase in cerebral oxygen extraction [48]. It is important to note that in these circumstances hyperventilation may also result in a decrease in cerebral blood flow usually due to a decrease in cardiac output, and that this decrease in cerebral blood flow may be associated with a reduction in cerebral oxygen extraction [48]. There is no indication that prophylactic mannitol is of benefit and its use should be reserved for specific evidence of intracranial hypertension. Osmotic therapy is ineffective in reducing intracranial pressure in the presence of renal failure [21] unless combined with ultrafiltration of twice the volume of infused mannitol. Other agents including barbiturates may significantly lower intracranial pressure but have profound haemodynamic side effects [35]. It is best considered as a bridge to transplantation to maintain stability while the patient awaits a donor liver.

CARDIOVASCULAR AND PULMONARY DISTURBANCES

Fulminant hepatic failure is associated with profound haemodynamic changes, most particularly, of a marked reduction in systemic vascular resistance. Over 50 % of patients have episodes of hypotension during grade 4 encephalopathy despite an elevated cardiac output, and these abnormalities are of prognostic importance. Despite the elevated cardiac index and arterial oxygen delivery to the tissues (cardiac index × arterial oxygen content, Da_{O_2}) Bihari and colleagues have proposed that an underlying covert tissue hypoxia is present [13]. Hyperlactataemia in the absence of systemic hypotension correlates inversely with systemic vascular resistance implying poor tissue perfusion despite apparently adequate delivery, and changes in the *in vivo* p50, a measure of the position of the oxygen–haemoglobin dissociation curve, are only associated with changes in peripheral oxygen extraction in patients who survive. In cases with an ultimately poor prognosis changes in *in vivo* p50 that might be expected to release more oxygen in the tissues are not associated with any change in oxygen extraction ratio, suggesting a profound disturbance in the control of peripheral circulation and oxygen homeostasis, with poor capillary perfusion [14]. This may result from an interruption to perfusion of some capillaries because of marginated platelets or activated white cells with a reflex arteriolar vasodilatation and luxury perfusion of remaining capillaries [15]. Increases in diffusion distance from capillary lumen to active respiring cells and a reduction in capillary transit time result in impaired oxygen extraction.

These patients exhibit a close relationship between oxygen delivery and oxygen extraction by the tissues. Such supply dependency has been proposed in other states with a high cardiac output/low vascular resistance, although its existence remains controversial. In patients with severe liver disease, use of a peripheral vasodilator such as prostacyclin (PGI_2) is associated with both an increased arterial oxygen delivery and oxygen consumption by the tissues [95]. Similarly NAC results in an increase in both oxygen delivery and oxygen extraction ratio [48]. Such a relationship between oxygen supply and extraction is also found at a tissue level. Changes in cerebral blood flow (using the xenon washout technique) are associated with corresponding changes in $CMRo_2$. Both PGI_2 and NAC increase cerebral oxygen delivery and $CMRo_2$, whereas hyperventilation and vasoconstrictor drugs (despite increasing mean arterial pressure) both reduce $CMRo_2$]96].

These findings carry important consequences for the management of patients with fulminant hepatic failure. Assessment of mean arterial pressure alone is inadequate and arterial oxygen delivery requires careful monitoring. Calculation of arterial oxygen content requires the use of a co-oximeter rather than a calculated arterial oxygen saturation because of significant changes in the position of the oxygen–haemoglobin dissociation curve. Haemodynamic goals of maintaining Da_{O_2} above 700 ml min^{-1} m^2, have been proposed. Other measures to maximize

Da_{O_2} should be attempted and the effect on oxygen extraction assessed.

Pulmonary complications may occur in up to 50% of cases [92]. The majority of cases have a low pulmonary vascular resistance and some increase in alveolar–arterial oxygen difference. In a recent review of cases with liver failure due to paracetamol hepatotoxicity, 33% had severe lung injury (Murray score > 2.5) with hypoxaemia contributing to the death of two patients [4]. Such hypoxaemia may have many causes including aspiration of gastric contents, pulmonary infection or a syndrome of non-cardiogenic pulmonary oedema. Chest radiology significantly underestimates the severity of the pulmonary dysfunction. Endotracheal intubation is usually undertaken when grade 3 encephalopathy occurs and care must be taken to ensure that changes in ventilatory parameters and end-expiratory pressure do not compromise systemic and cerebral haemodynamics.

ELECTROLYTE AND RENAL DYSFUNCTION

Hyponatraemia is a universal finding as a result of water retention and an intracellular sodium shift from inhibition of membrane Na/K ATPase. Saline should not be administered. Hypokalaemia related to the respiratory alkalosis, and hypophosphataemia [28] may also require correction. Hypoglycaemia due to reduced hepatic glycogen stores and hyperinsulinaemia require treatment with continuous glucose administration. Hyperlactataemia and metabolic acidosis occur in up to 30% of cases, predominantly paracetamol induced, and carry a very poor prognosis.

Either acute tubular necrosis or functional renal failure may occur in up to half of all cases [97]. In cases of toxic injury caused by paracetamol, carbon tetrachloride or solvent use, renal impairment may be out of proportion to the hepatic injury. Continuous haemodiafiltration is performed in order to minimize large shifts in solute [98]. Large changes in serum sodium concentration must be avoided particularly at the time of orthotopic liver transplantation, as osmotic demyelination and central pontine myelinolysis may result.

BACTERIAL AND FUNGAL SEPSIS

A wide range of defects in host defences is present. Impaired opsonization, leucocyte chemotaxis [100] and intracellular killing [22] all contribute to a substantial risk of sepsis with up to 80% of patients developing bacterial sepsis and 30% developing fungal infection [83]. The sensitivity and specificity of the usual markers of infection are poor. The majority of infective episodes are related to Gram-positive organisms. Prophylactic antibiotics may have a minor role, although there is no evidence that enteral decontamination is of any benefit [82]. More important is close microbiological surveillance.

Fungal infection is particularly common in cases with prior bacterial sepsis, a low white cell count at presentation and renal failure. Patients require careful monitoring particularly in those proceeding to orthotopic liver transplantation.

DISORDERS OF COAGULATION AND FIBRINOLYSIS

Hepatocellular necrosis results in marked impairment in synthesis of many coagulation factors and their inhibitors, as well as those factors involved in the regulation of fibrinolysis. Only factor VIII concentrations are elevated. In addition to the reduced synthesis, the contribution of increased intravascular consumption of coagulant factors has been controversial for some years, but the recent finding of elevated thrombin–antithrombin III complexes and D-dimer concentrations both indicate intravascular activation of coagulation [58]. In contrast, activation of fibrinolysis is not a significant clinical problem [77].

Progressive thrombocytopenia is universal, associated with the loss of the larger more haemostatically active platelets [85]. Platelets also have reduced aggregation to ADP.

Assessment of prognosis

Improvements in intensive medical management have resulted in a steady increase in survival rates from fulminant hepatic failure. Previous studies have demonstrated that the severity of the liver failure assessed by serial prothrombin times, number and type of organ system failures, and the aetiology of the hepatocellular necrosis are all important [10]. Assessing which patients have the worst prognosis and require consideration for other interventions, including orthotopic liver transplantation, must be undertaken early giving enough time to find an appropriate donor, and at a time when the patient is fit enough to withstand the procedure.

The King's College group has proposed that assessments of prognosis will be different for each aetiology [71]. Paracetamol-induced hepatotoxicity is best assessed by the presence of acidosis (arterial pH < 7.3) and level of prothrombin time [76] (table 4). For all other aetiologies two static variables, age and aetiology, as well as dynamic variables of bilirubin, prothrombin time and time from onset of symptoms to development of encephalopathy are used (table 4). In contrast, Bernau and colleagues proposed that factor V concentrations and age were more discriminatory [10], and a recent study from

Table 4 Criteria for consideration for orthotopic liver transplantation

Paracetamol overdose
  Arterial pH < 7.30
  or all the following
  Prothrombin time > 100 s
  Creatinine > 300 μmol litre^{-1}
  Grade 3 or 4 encephalopathy
  Prothrombin time increasing on day 4
Non-paracetamol overdose
  Any three of the following:
  Aetiology non-A–non-B hepatitis, halothane or drug reaction
  Age < 10 or > 40 years
  Jaundice to encephalopathy
  Serum bilirubin > 300 μmol litre^{-1}
  Prothrombin time > 50 s
  or prothrombin time > 100 s

(Taken from ref. [71])

Table 5 Results of orthotopic liver transplantation for fulminant (FHF) and late onset hepatic failure (LOHF)

	% Grade 3/4			
Author [Ref.]	Patients	FHF/LOHF	Encephalopathy	% Survival
O'Grady [69]	31	16/15	35	61
Vickers [94]	16	16/0	100	56
Schafer [86]	24	24/0	50	58
Emond [32]	19	19/0	84	58
Iwatsuki [53]	42	42/0	64	50
Gallinger [37]	21	9/12	81	72
Rakela [79]	8	8/0	88	63

Japan could not confirm the King's College criteria [91], perhaps reflecting differences in aetiology and medical management.

Each centre needs to develop criteria that can predict outcome as accurately as possible and use these to refer cases for orthotopic liver transplantation. This procedure is usually not performed in patients over the age of 65 years, and does require a satisfactory cardiopulmonary assessment.

Orthotopic liver transplantation

For those patients with the worst prognosis orthotopic liver transplantation remains their only chance of long-term survival. Survival rates of up to 70% have been reported in some series (table 5). Selection of the patient is important [99]. An upper age limit of 65 years is used in some units and the presence of two other organ system dysfunctions used as a contraindication. Reports of significant brain damage after transplantation related to preoperative cerebral ischaemia and cerebral oedema reflects the difficult issue of the significance of changes in cerebral blood flow and perfusion pressure in predicting neurological outcome [68]. Recent studies have demonstrated that survival without neurological deficit may occur even after periods of up to 3 h of low cerebral perfusion pressure presumably because of very low $CMRo_2$. Possibly the use of jugular bulb cannulation and lactate/oxygen concentrations may give better discrimination.

In those cases with potentially reversible liver dysfunction, such as paracetamol hepatotoxicity, the technique of auxiliary partial orthotopic liver transplantation with a hemihepatectomy of donor and recipient, and grafting of the left lobe of the donor only, have theoretical advantages [19]. If satisfactory regeneration of the native liver occurs then immunosuppression can be withdrawn and the graft then atrophies [64].

Artificial liver support

In recent years the use of temporary liver support with perfusion of hepatocyte or hepatoblastoma cell lines encapsulated within hollow fibres has seen a resurgence of interest [84, 90]. Their use remains experimental and no evidence of survival advantage or basis for a "bridge" to transplantation has been reported. Previous techniques including high flux haemofiltration, charcoal haemoperfusion [39, 70] and Amberlite XAD-7 perfusion [51]; all had some problems of bioincompatibility and were clinically ineffective. Indeed, the concept that the major problem in the late stages of fulminant hepatic failure is the result of the failure of the liver to clear "toxins" may be false. Studies demonstrating dramatic improvements in cerebral perfusion pressure, and systemic vascular resistance on exclusion of the liver from the circulation or hepatectomy, suggest that substances released by the necrotic organ may be just as important. Until more efficient biocompatible devices are available, artificial liver support will develop only slowly.

New approaches to acute lung injury

L. M. BIGATELLO AND W. M. ZAPOL

The lung responds to acute injury of diverse aetiology via a series of common pathways. The pathological changes caused by a variety of toxic and infectious agents evolve over time from endothelial and epithelial injury to alveolar consolidation and finally to fibroblast proliferation and collagen deposition. Widespread acute injury to the lung produces *diffuse alveolar damage* [33], a well characterized anatomical entity that forms the basis of the protean clinical picture of acute respiratory failure. This clinical picture has been identified in the past by a host of terms, creating some confusion. Recently, a panel of experts clarified the definition of acute lung injury [4]. The terms acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) are proposed to describe the continuum of a syndrome of primary respiratory failure, characterized by the acute onset of dyspnoea, hypoxaemia and bilateral consolidation on the chest radiograph (table 1). ALI is considered to be the early stage of ARDS, with milder abnormalities of respiratory function, and it may subsequently evolve into the more severe and more easily diagnosed syndrome of ARDS. The major reason to define ALI is to facilitate experimental and clinical investigation of the early stages of ARDS, in order to improve the early recognition and treatment of this syndrome [4].

Aetiology of ALI and ARDS

There are many known aetiological factors of ARDS. Although little information exists regarding the causes of ALI itself, it seems likely that the aetiologies causing ARDS also cause ALI [4]. The common aetiologies of these syndromes are summarized in table 2. Rather than listing all the known causes, we have emphasized two main aetiological groups, separating causes that arise within the lung from those arising outside the lung. The subsequent anatomical and physiological pattern of lung injury evolves via common pathways, and respiratory failure dominates the clinical presentation. Co-existing acute lung disease may at times cloud the acute onset of respiratory failure; nosocomial pneumonia in particular is both a frequent cause and complication of ALI and presents a diagnostic challenge. It is currently accepted that a syndrome of ALI can develop in patients with co-existing lung disease [4]; at times [52] certain lung pathology, such as interstitial lung disease, pulmonary embolism, invasive carcinoma and *Pneumocystis carinii* pneumonia are excluded from clinical trials of ARDS since they would probably increase the mortality or alter the host's response to ARDS. The incidence of each individual aetiological factor varies widely according with the ICU population under study. In general, medical intensive care units most often treat patients with ALI caused by infectious pneumonia, often with pre-existing chronic lung disease, while surgical intensive care units treat ALI after trauma, burns and abdominal sepsis.

Regardless of whether the primary aetiology originates within or outside the lung, a systemic inflammatory response accompanies and may determine the progression of ALI (table 3). Chemotaxis and activation of leucocytes lead to the release of cytotoxic free radicals and cytokines such as tumour necrosis factor and the interleukins [12]. The expression of leucocyte adhesion molecules and proteases [14] contributes to epithelial and endothelial injury. A number of homeostatic systems are activated: the complement and kinin systems, the coagulation cascade, the cyclo-oxygenase and leukotriene pathways and the nitric oxide (NO)-cyclic guanosine monophosphate (cGMP) pathway. The systemic inflammatory process contributing to acute lung injury is complex. We will highlight a few recent and significant findings.

Complete inhibition of local fibrinolysis has been demonstrated in the broncho-alveolar lavage fluid of patients with ARDS but not in the fluid of patients with other forms of acute respiratory failure [7]. The sites of early fibrin and fibronectin deposition in alveoli correlate with the sites of formation of hyaline membranes, the anatomical hallmark of ARDS [33], and the subsequent location of fibrosis and collagen deposition.

Increased local production of NO by inducible NO synthase during sepsis may impair local hypoxic pulmonary vasoconstriction (HPV), impair ventilation to perfusion matching and reduce arterial oxygen tension [54]. In contrast, when low concentrations of NO gas are administered by inhalation, (see section on supportive therapy), NO primarily reaches ventilated alveoli, augments their perfusion and enhances ventilation to perfusion matching,

Table 1 The definition of acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) according to the American-European Consensus Conference of ARDS [4]

(1) Acute onset of respiratory distress
(2) Hypoxaemia:
  ALI: $Pa_{O_2}/FI_{O_2} \leqslant 300$ mm Hg
  ARDS: $Pa_{O_2}/FI_{O_2} \leqslant 200$ mm Hg
(3) Bilateral consolidation of chest radiograph
(4) Absence of clinical findings of cardiogenic pulmonary oedema

Table 2 Aetiologies of acute lung injury (ALI) and acute respiratory distress syndrome (ARDS). (Aetiologies specific for ALI have not been investigated separately. Since ALI and ARDS are believed to form an anatomical and clinical continuum, the aetiologies of ARDS are extended to ALI)

(1) *Direct lung injury*
  Aspiration pneumonitis
  Other pneumonitis: oxygen, smoke inhalation, radiation, bleomycin
  Infectious pneumonia, community acquired and nosocomial
  Trauma: lung contusion, penetrating chest injury
  Near-drowning
  Fat embolism
(2) *Distant injury*
  Inflammation, necrosis, infection (sepsis syndrome)
  Multiple trauma, burns
  Shock, hypoperfusion
  Acute pancreatitis
  Transfusion-associated lung injury (TRALI)

increasing the arterial oxygen tension [47]. Regional inhibition of NO synthesis may also occur in the sepsis syndrome, promoting vasoconstriction, platelet aggregation and thrombosis; the biological production and effects of NO are widespread and both inhibition and induction of NO synthesis may occur simultaneously in different organ systems at varying times during systemic inflammation [35].

Activation of the cyclo-oxygenase pathway may increase the synthesis of vasoconstrictor prostaglandins (e.g. thromboxane A_2) resulting in pulmonary hypertension, oedema and increased bronchial reactivity. Clinical use of a cyclo-oxygenase inhibitor in patients with ARDS and the sepsis syndrome is currently being investigated [3].

Pathophysiology of ALI and ARDS

ANATOMY

The pathological evolution of ALI and ARDS in animal models has been separated into two discrete phases: an exudative and a proliferative phase. In humans, however, this sequence is not well separated temporally, and exudative and fibrotic regions of the lung often overlap as disease progresses. After the initial acute epithelial and endothelial injury, alveolar oedema, haemorrhage and fibrin deposition occur in the lung, along with a diffuse interstitial inflammatory cell infiltrate (fig. 1). Alveolar exudation is widespread despite a low hydrostatic pressure in the pulmonary vessels: injury rather than an elevated pressure promotes oedema during early ALI. As hyaline membranes progressively line the alveolar spaces, alveolar consolidation results. These anatomical phenomena form the basis for the physiological events of hypoxaemia and reduced compliance. They also justify the logic of the beneficial effect of positive pressure ventilation in promoting alveolar recruitment and, at the same time, explain the exquisite susceptibility of the injured alveolar space to the additional noxious stresses of mechanical ventilation [15]. Early pulmonary vascular lesions include haemorrhage and the formation of microthrombi in capillaries and small pulmonary arteries; later, medial hyperthrophy and intimal fibrosis occur, and eventually large portions of the pulmonary vascular bed may become obliterated [58]. As the syndrome progresses, fibroblast proliferation becomes prominent. Peribronchial and interstitial fibrosis, with variable degrees of chronic inflammation, are characteristic. Fibrosis is at times exceptionally severe (honeycomb lung) and their intensity appears to correlate with a poor prognosis [33].

PHYSIOLOGY

Arterial hypoxaemia and a low lung compliance are the clinical hallmarks of ALI. Alveolar collapse causes hypoxaemia by impairing the matching of ventilation to perfusion. The pulmonary circulation

normally responds to hypoxaemia by locally constricting blood vessels supplying poorly ventilated alveoli, thereby diverting venous blood flow to well ventilated alveoli. This response, termed hypoxic pulmonary vasoconstriction (HPV), is a homeostatic response required to preserve an adequate arterial oxygen tension. Unfortunately, the combination of HPV, release of vasoconstrictor mediators and down-regulation of the production of vasodilators such as NO and prostacyclin may enhance pulmonary hypertension, which fosters the formation of pulmonary oedema and increases the afterload of the right ventricle. Severe pulmonary hypertension is associated with a high mortality [61]. Vasoconstriction, vascular occlusion and alveolar overdistension by positive pressure ventilation can create lung regions with a high ventilation to perfusion ratio and markedly increase the ventilatory dead space of patients with established ARDS. This augments the ventilatory requirements and increases the risk of alveolar damage due to mechanical forces.

During ARDS, the compliance of the lung is initially decreased by alveolar oedema and collapse, and subsequently by diffuse pulmonary fibrosis. Although a low compliance is not universally included as a diagnostic criterion of ARDS, it is a constant feature of the syndrome and requires accurate evaluation to optimize mechanical ventilatory support:

Compliance of the respiratory system

$$= \frac{V_T}{Paw - \text{total PEEP}} \quad (1)$$

Compliance of the lung

$$= \frac{V_T}{(Paw - Poes) - \text{total PEEP}} \quad (2)$$

where *P*aw and *P*oes are the pressures measured during a 2-s end-inspiratory pause (plateau pressure) at the airway and oesophagus respectively; total PEEP is the sum of both applied and intrinsic positive end-expiratory pressure (auto-PEEP) [46]. The determination of respiratory compliance in patients with ARDS should include:

(a) measurement of plateau pressure at several lung volumes;
(b) measurement of auto-PEEP;
(c) when deemed necessary, measurement of intrathoracic pressure, to separately evaluate lung and chest wall compliance.

Methods currently employed to assess static respiratory compliance deliver small incremental volumes to a sedated and fully relaxed patient. A series of inflations are used to compute a pressure–volume curve, the slope determining the compliance of the respiratory system. To separate the lung and chest wall contributions, intrathoracic pressure is estimated with an oesophageal balloon. During ALI the compliance of the respiratory system is assumed to be primarily determined by lung compliance. Occasionally, chest wall compliance is reduced (e.g. abdominal distension, circumferential burns, tight bandages or massive oedema of the trunk) and measurement of oesophageal pressure is necessary to determine lung and chest wall compliance.

Significant increases of airway resistance are atypical of established ARDS, which is primarily viewed as a syndrome of reduced compliance. However, an increased resistive component [27] should be sought in the early phases of ALI, when bronchial inflammation is apparent and bronchoconstrictor mediators may be released.

Prognosis

When ALI progresses to established ARDS, a mortality rate near 60% has been reported consistently [1, 2, 8, 43, 52, 62]. The patient's prognosis is worsened by risk factors such as advanced age, pre-existing diseases and sepsis, regardless of whether the latter is the cause or a complication of

Table 4 Incidence and mortality rate of the acute respiratory distress syndrome (ARDS) in three studies: the NIH collaborative study of extracorporeal support [62], the European collaborative study of ARDS [1] and the Multicenter Registry of patients with ARDS [52]. (* Since the diagnosis of sepsis includes patients with infectious pneumonia, the total incidence of the individual aetiological factors is greater than 100%)

	Incidence (%)			Mortality (%)

ARDS. The combination of two or more such risk factors (e.g. age over 60 and sepsis) with ALI can raise the mortality rate to 70–90%. Table 4 summarizes the incidence and prognosis of the most frequent aetiologies of ALI, as reported in three large clinical studies over the past two decades: the NIH collaborative study of extracorporeal support [62], the European collaborative study of ARDS [1] and the Multicenter Registry of patients with ARDS [52]. Even though the entry criteria of the most recent of these studies [52], are rather liberal and approach the current definition of ALI [4], the frequency and mortality rates of each aetiological category of ARDS were comparable in all three studies. Figure 2 illustrates the distribution of the most common aetiologies of ARDS in the European Collaborative Study [1]. Figure 3, obtained from the data of the Multicenter Registry of patients with ARDS [52], illustrates the direct correlation of mortality with increasing age, as well as with the number of aetiological factors causing ALI present at the time of diagnosis. The development of new organ system failures (e.g. liver failure, renal failure) during the evolution of ALI greatly increases the mortality rate, reaching 80–90% when more than three organ systems fail [1].

An increasing survival rate of patients with ARDS has recently been suggested, using temporal survival trend analysis [41, 43]. While the survival rate of high risk patients (i.e. those with advanced age or multiple risk factors) is essentially unchanged from earlier periods, younger patients, after traumatic injury and without overt infection, appear to have a significantly better chance of survival when compared with 10 or 20 years ago. This may be a reflection of an overall improvement of intensive care therapies for all critically ill patients, improved ventilatory and pharmacological support, or all three. Not all studies, however, report enhanced survival rates [52] and careful, prospective data collection is needed.

For the survivors of ARDS, lung function often recovers significantly, allowing the survivors of this devastating syndrome to lead a productive life. The degree of residual impairment of respiratory function correlates with the severity of ARDS [39]. After a prolonged hospital course, recovery of lung function (both subjective function and spirometry) continues for several months, and plateaus at 3–6 months. At this time, the total lung capacity, vital capacity and DL_{CO} reach approximately 70% of the predicted normal values [39].

Therapeutic approaches to ALI

There is widespread agreement on the basic therapeutic principles for treating ALI: admission to the ICU, treatment of the underlying condition, use of supplemental oxygen and mechanical ventilation with PEEP, avoidance of oxygen toxicity and of fluid overload. Beyond this, practices vary widely. We will discuss both common and novel therapies.

PREVENTION AND TREATMENT OF THE UNDERLYING CONDITION

Limiting the incidence and severity of the various aetiologies known to cause ALI is the most sensible way of preventing ARDS. Since ARDS is a relatively uncommon occurrence (5 to 25 cases per 100000 individuals per year) [34, 55] any prospective evaluation of preventive measures requires a large number of subjects. One way to overcome this problem in planning studies of ARDS is to select a patient population known to be at high risk of developing the syndrome [11]. Another approach is to liberalize the definition of ARDS and thereby increase its rate of diagnosis. This strategy was promoted at the American-European Consensus Conference on ARDS [4] and prompted the introduction of the term ALI to include earlier and less severe forms of ARDS.

General principles of sound clinical practice are important for the prevention of ALI: early drainage of abscesses, debridement of devitalized tissue, rapid fixation of fractures, grafting of burn scars, adequate volume resuscitation of hypovolaemic states, appropriate use of antibiotics and sterile techniques, etc. Certain additional interventions aimed at limiting the incidence or severity of ALI have been proposed.

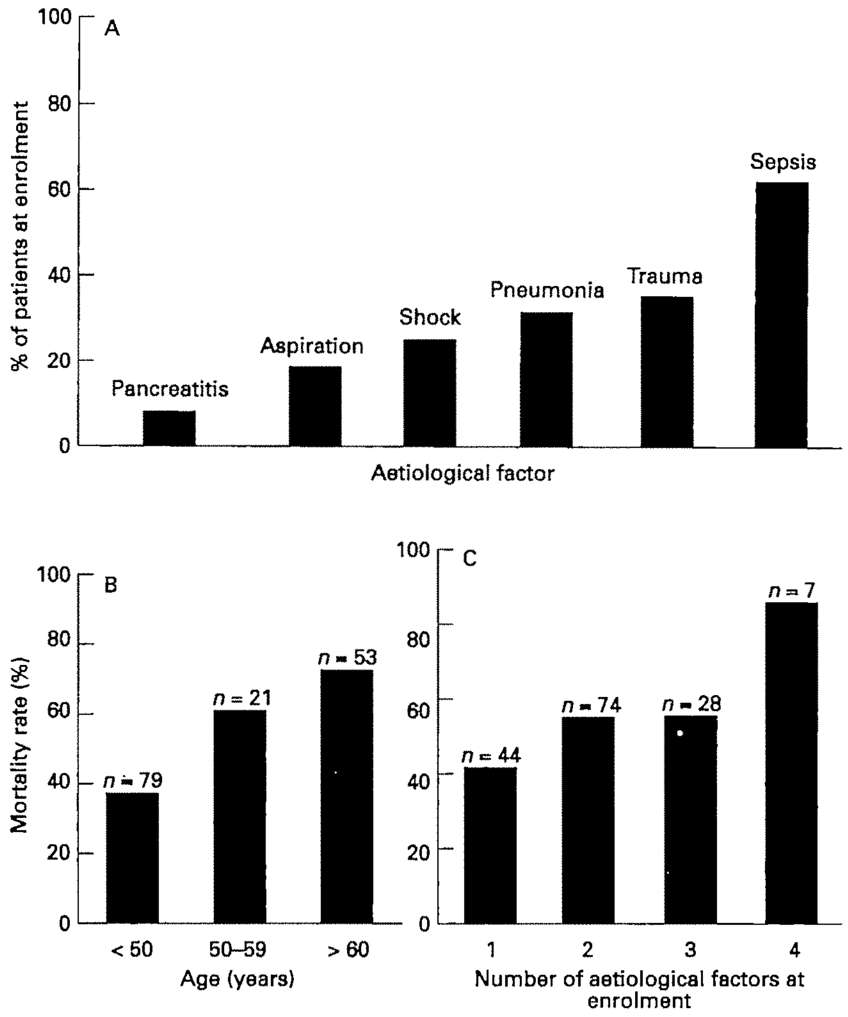

Figure 3 Predictors of mortality rate in a prospectively studied population of 153 patients with acute lung injury/acute respiratory distress syndrome. Modified with permission from Sloane and colleagues [52]. A: shows the incidence of some of the most common aetiological factors; more than one aetiological factor was often recorded. B: shows the effect of increasing age on the mortality rate. C: shows the effect on the mortality rate of the combination of multiple aetiological factors at the time of enrolment.

"Supranormal" haemodynamic management

The practice of "supranormal" [51] haemodynamic resuscitation with i.v. fluids and pressors has been proposed to improve the therapy of critically ill patients, including those with ARDS [10, 13]. A hidden tissue oxygen debt, unmasked by "supranormal" resuscitation, was suggested to negatively affect the prognosis of ARDS and several other critical illnesses. Despite enthusiasm for this approach in the treatment of trauma victims and septic patients, its effect is controversial [50]. Two large recent trials [24, 29] of critically ill patients, including ARDS patients, showed no benefit of "supranormal" resuscitation on the overall survival rate or the evolution of respiratory failure.

Prophylaxis of chemical and bacterial aspiration

Aspiration of gastric contents is a frequent aetiology of ALI. Prophylaxis includes watchful assessment of the patients' ability to protect the airway, skilful airway management at the time of and after tracheal intubation, and possibly (controlled data are not available) stimulation of gut motility with cholinergic agents such as metoclopramide. In addition, pharmacological interventions have been examined to learn if they reduce the incidence of nosocomial pneumonia and consequent ARDS through decontamination of the gastrointestinal tract. Oral or gastric administration of sucralphate (a sucrose sulphate and aluminium hydroxide salt) for stress ulcer prophylaxis prevents Gram-negative bacillary overgrowth of the proximal gastrointestinal tract of intubated patients and may decrease the incidence of nosocomial pneumonia in comparison with therapy with antacids and histamine receptor antagonist [18]. Selective gastrointestinal decontamination with non-absorbable antibiotics has also been proposed to prevent aspiration of bacteria into the tracheobronchial tree. However, clinical trials failed to show a decreased incidence of nosocomial pneumonia following selective decontamination [22].

Prophylaxis of transfusion-related ALI (TRALI)

TRALI may occur when human leucocyte antibodies (HLA) are transfused via a plasma-containing blood product, i.e. fresh frozen plasma, whole blood or packed red blood cells [20]. The combination of these antibodies with the host's marginated pool of granulocytes (the majority of which reside in the lung) activates the complement pathway generating an inflammatory reaction leading to ALI. Characterization of the pathogenesis of TRALI is recent. What was previously considered to be a risk factor for ARDS, massive blood transfusions, is probably TRALI. The incidence of TRALI is unknown since patients who develop ALI after blood transfusions often have other risk factors capable of producing lung injury and it is often difficult to isolate a single responsible aetiology. A laboratory diagnosis of TRALI is supported by HLA antibody screening of the donor blood. Prevention of TRALI [20] may be possible through donor selection and pre-testing: multiparous women and previously transfused subjects are most likely to donate HLA antibodies.

Anti-inflammatory therapy: corticosteroids

Several clinical trials of corticosteroid therapy for the treatment of early sepsis and the treatment or prevention of ARDS were conducted in the past decade [5, 11]. A sub-study of a large sepsis trial [11] prospectively evaluated the effects of 24 h of treatment with methylprednisolone, 30 mg kg^{-1} i.v. every 6 h, on the development of ARDS in patients with the sepsis syndrome. They found no beneficial effect; in fact, greater mortality occurred in the treated group. Another large study [5] failed to detect any benefits of a similar methylprednisolone regimen for the treatment of established ARDS. Despite these negative results, corticosteroid therapy has been proposed for the treatment of the late fibroproliferative phase of ARDS [40]. There are no controlled data to support this approach. On the other hand, there are risks, chiefly an increased susceptibility to infection [11, 40].

Anti-inflammatory therapy: immunological agents

New pharmacological agents aimed at blocking the mediators of the inflammatory response have been tested in the laboratory and clinical trials. Various monoclonal antibodies directed against endotoxin or cytokines, as well as naturally occurring antagonists of cytokine receptors, have been studied. A clear synopsis of the status of this complex field has been published [3]. Most of the clinical trials thus far completed were directed at treating the large group of patients with the sepsis syndrome and provided few data regarding their effects upon respiratory parameters. In one study, a prospectively defined analysis of a subgroup of patients with ARDS was included [8] and reported no effect of a human anti-endotoxin monoclonal antibody on the survival or resolution of ARDS. The results of most clinical trials of immunotherapy have thus far been disappointing [3] and no agent aimed at blocking the immunological response of septic critically ill patients is available. A broader and less selective approach to immunotherapy employs the use of anti-inflammatory agents that have well known pharmacological and safety profiles. One of these agents, the cyclo-oxygenase inhibitor ibuprofen, has produced encouraging results in a phase II trial of septic patients [6]. A large, multicentre trial of i.v. ibuprofen (10 mg kg^{-1} every 6 h for 48 h) in patients with the sepsis syndrome and related ARDS has recently been completed [3].

SUPPORTIVE THERAPY

Significant progress has taken place in the past 10 years in the area of supportive therapy for acute respiratory failure. Although these advances have not been clearly shown to improve the overall survival rate of patients with severe ARDS, we believe they have contributed to our ability to care for these patients and our knowledge of the syndrome.

A novel approach to mechanical ventilation

The traditional manner of ventilating patients with ALI delivers large tidal volumes (10 to 15 ml kg^{-1}), minimizes inspired oxygen fraction ($F_{I_{O_2}}$) and maintains normal arterial oxygen and carbon dioxide tensions. Significant changes of this practice have been proposed based upon increased understanding of the traumatic effects of mechanical ventilation on the lung [37, 53]. Lung tissue damage from mechanical ventilation was demonstrated early after the widespread introduction of positive pressure ventilation for acute respiratory failure [45], but the implication of these early data became clearer 20 years later, when studies from Europe [15] and the USA [56] provided unequivocal evidence of severe lung damage produced in normal animals by large inflation volumes (*volotrauma*). A further line of research underscored the importance of volotrauma by demonstrating that during early ALI the recruitable lung volume is significantly reduced. By imaging the lungs of early ARDS patients with high resolution computed tomography (CT), the parenchyma revealed surprisingly inhomogeneous lesions [26, 38], with areas of consolidation in dependent lung regions and areas of normal radiographic density in non-dependent regions (fig. 4). By combining traditional physiological analysis with CT imaging, Gattinoni and colleagues [26] reported that the mechanical properties of the lung were similarly inhomogeneously distributed: areas of consolidation had a significantly reduced compliance whereas lung regions that appeared normally aerated had a normal compliance. Thus, a tidal volume of 10–15 ml kg^{-1} may be excessive when the portion of lung parenchyma susceptible to recruitment is only 30 % of the total lung mass.

While the main determinant of volotrauma is the lung volume at end inspiration [16], this cannot be routinely measured, and airway pressure is commonly employed to estimate the degree of distension associated with tidal ventilation. Lung tissue trauma may occur if the lung is underinflated and alveoli collapse at end expiration: it is also believed that cyclic alveolar opening and closing during tidal breathing may induce tissue and surfactant damage [44]. It seems ideal, therefore, to attempt to individually determine the appropriate lung volume at which each patient with ALI should be mechanically ventilated to produce the least volotrauma. The ideal

ventilatory pattern may be determined by constructing a pressure–volume curve of the respiratory system (or the lung when indicated) as previously described. A number of studies [17, 19, 26, 44, 49] indicate that the static pressure–volume curve of the respiratory system during ARDS is sigmoid-shaped, with both lower and higher "inflection points" denoting the range of pressure and volume at which the tidal ventilation should be delivered to minimize volotrauma: a PEEP level of 10–15 cm H_2O and an end-inspiratory plateau pressure of 30 to 35 cm H_2O are sufficient in most circumstances to avoid both alveolar collapse and overstretching. Roupie and colleagues [49] obtained static pressure–volume curves in patients with and without ARDS. They demonstrated that in patients with mild respiratory failure the curves were steep and linear, not differing from normal compliance curves of the respiratory system. In contrast, for patients with ARDS the pressure–volume curve was shifted to the right and in most cases displayed both low and high "inflection points" occurring at approximately 10 and 30 cm H_2O inspiratory plateau pressure, respectively. Figure 5 shows an idealized pressure–volume curve of the lung during ARDS, with a reduced slope and two inflection points, and it clearly contrasts with a normal compliance curve.

At times, limiting the peak inflation pressure (and thus the end-inspiratory volume) below the high inflection point of the pressure–volume curve may only be accomplished by markedly reducing the tidal volume (e.g. $\leqslant 6$ ml kg^{-1}) in which case hypercarbia ensues at normal respiratory rates. The growing clinical practice of allowing the arterial carbon dioxide tension to rise gradually, providing enough time for renal compensation of the respiratory acidosis by retaining anions, has been given the term *permissive hypercapnia* [19]. Despite widespread enthusiasm, there is presently no evidence that this style of ventilatory management improves the outcome of patients with ALI.

INHALED NITRIC OXIDE

Nitric oxide (NO) is a potent endogenous vasodilator, produced in endothelial cells by cleavage of the amino-acid L-arginine by the various isoforms of

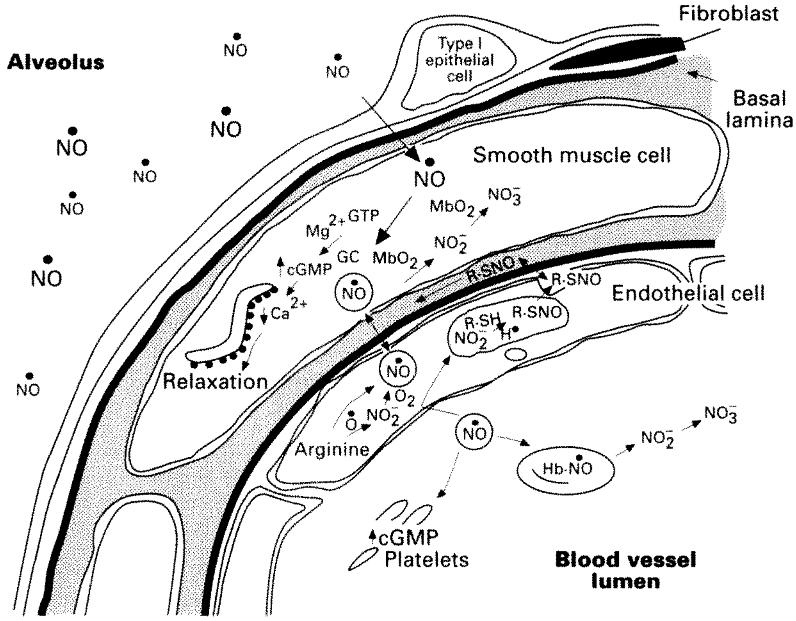

Figure 7 Effects of inhaled nitric oxide (NO) on acute pulmonary hypertension associated with acute respiratory failure. (Reproduced with permission from Frattacci and colleagues [21].)

NO synthase [42]. Nitric oxide is an unstable free radical that accounts for the activity of endothelium-derived relaxing factor as well as for other important biologic activities [23, 42]. The vasodilator action of NO (fig. 6) is mediated through an increase of cGMP within the smooth muscle cells of the vascular wall. Other cGMP-mediated properties of NO include the modulation of neurotransmission, bronchodilatation and inhibition of platelet aggregation. When exogenous NO gas is inhaled (fig. 7) it produces profound local vasodilatation in ventilated regions of the lung and reverses the pulmonary vasoconstriction due to hypoxaemia (HPV) and other vasoconstrictor stimuli [60]. In tissues, NO rapidly degrades to nitrates and nitrites with little biological activity. When NO diffuses into the blood vessels, it combines rapidly with circulating haemoglobin and is inactivated. The resulting nitrosyl–haemoglobin is oxidized to methaemoglobin. These biological properties make NO an ideal agent to produce selective pulmonary vasodilatation without inducing systemic vasodilatation. Furthermore, producing selective vasodilatation of well ventilated areas of the pulmonary vasculature improves the matching of ventilation to perfusion [47]. Following the earliest clinical trials of NO inhalation in patients with ARDS [9, 48], a number of centres in the USA and Europe have administered NO under investigational protocols as part of the treatment of ALI. The current status of this innovative therapy can be summarized as follows.

In approximately 70 % of patients with established ARDS, when breathing NO the arterial oxygen tension increases and pulmonary hypertension decreases by at least 20 % of baseline [36]. This response is sufficient to allow a decreased level of ventilatory support, reducing either the $F\text{I}_{O_2}$ or PEEP level. ARDS patients most likely to respond favourably are those with a high pulmonary vascular resistance [9, 36]. Very low inhaled NO concentrations are sufficient to elicit a significant increase of the Pa_{O_2}: 5 to 20 parts per million (ppm) [9, 48]. Toxicity is minor or unmeasurable at low inspired NO concentrations [23]. The effect of NO treatment on outcome is unknown; results from large randomized trials of NO inhalation in ARDS patients in Europe and North America will be available in several years.

EXTRACORPOREAL TECHNIQUES OF GAS EXCHANGE

Extracorporeal membrane oxygenation (ECMO) for acute respiratory failure was introduced to clinical practice about 25 years ago. The concept behind the use of ECMO in patients with acute respiratory failure is to provide a temporary "substitute" for transpulmonary respiration while the severely injured lungs are allowed to recover. After initial, anecdotal reports of positive results, a multicentre trial sponsored by the National Institutes of Health (NIH) failed to show any advantage of veno–arterial ECMO over traditional mechanical ventilation in severe ARDS [62]. In the ensuing years, technical progress has made the practice of ECMO safer and less cumbersome, and several centres throughout the world have acquired great skill, reporting excellent results. A second NIH-sponsored trial was designed to test the effect of a newer mode of extracorporeal gas exchange, extracorporeal carbon dioxide removal provided via veno–venous perfusion. Unfortunately, this trial also failed to show any significant benefit over traditional mechanical ventilation [43]. The practice of extracorporeal gas exchange in adults remains limited to a few, highly specialized centres in the USA and Europe.

Surfactant

Replacement therapy with lung surfactant has been pursued for the treatment of ALI, particularly when aspiration pneumonitis is the suspected aetiology.

Both natural and synthetic preparations are being studied. There is evidence that pulmonary surfactant is dysfunctional in animal models of aspiration pneumonitis as well as in adults with ALI [28]. Despite highly successful use of surfactant therapy in newborns with the respiratory distress syndrome and evidence for favourable physiological responses in animal models, as well as preliminary clinical observations [57], there are no clinical trials to support the use of surfactant in adults with ALI.

OTHER EXPERIMENTAL TECHNIQUES

The *intravenous oxygenator* (IVOX) is a device composed of a bundle of hollow polypropylene fibres, inserted percutaneously into the inferior vena cava, where venous blood flows over the hollow fibres and oxygen and carbon dioxide are exchanged. Only preliminary data from the FDA phase II trial are available. With the present technology the IVOX does not seem to make a significant impact upon gas exchange in severe ARDS [30].

Partial *liquid ventilation* requires ventilation of the lungs with perfluorocarbon. The high density and low surface tension of perfluorocarbon enhances the recruitment of dependent lung regions, improves ventilation to perfusion matching and favours the removal of airways secretions. Only very preliminary data regarding safety and suitability of this technique in ARDS are available [31]. More encouraging data have been reported in a small number of infants and children with severe acute respiratory failure treated with perfluorocarbon [31].

Conclusions

Acute lung injury of multiple aetiologies may lead to a severe form of acute respiratory failure, the acute respiratory distress syndrome (ARDS). The mortality rate of ARDS is very high, despite the scientific and technological advances in the care of critically ill patients of the past 30 years. Recent data, however, suggest that the prognosis of ARDS has improved in selected populations, particularly younger patients without overwhelming infection. These observations, together with our growing knowledge of the pathophysiology of acute respiratory failure, should encourage investigators and clinicians to continue their efforts to better understand and treat acute lung injury. Future directions of research and clinical activity in this field include:

(a) Early intervention. Treatment of the underlying aetiology, maintenance of adequate organ perfusion and appropriate ventilatory management may reduce the incidence of infection and of iatrogenic complications and thereby increase survival. New experimental approaches such as nitric oxide inhalation and permissive hypercapnia should be targeted at the earliest stages of acute respiratory failure.

(b) Researching the earliest humoral and cellular mechanisms producing the initial acute injury may provide clinicians with future therapies to apply early in the course of acute respiratory failure.

(c) Clinical trials of novel and promising therapies should be designed by experienced clinical investigators. Trials should include adequate numbers of patients with ARDS of similar aetiology, include multiple institutions and, ideally, they should be sponsored by an impartial agency. The next few years will be exciting ones for those clinicians and investigators who are interested in the treatment of ALI and ARDS, because the results of several clinical trials will become available. The ibuprofen study should soon be published. Two large clinical trials of inhaled nitric oxide are under way. A 7-year, multicentre programme has been funded by the NIH to implement large scale clinical trials of novel treatments for ARDS. The first of such studies will compare traditional, large-tidal volume ventilation with reduced tidal volumes and airway pressures.

Sepsis and cytokines: current status

T. S. BLACKWELL AND J. W. CHRISTMAN

Sepsis syndrome represents a spectrum of pathophysiology that results from an exuberant host inflammatory response to a specific inciting event. The clinical course of sepsis syndrome ranges from mild physiological derangements to severe multiple organ dysfunction and death. In the United States, the incidence of sepsis syndrome has been estimated at 400000 cases annually, with a fatality rate of nearly 40%. The development of sepsis syndrome is related to a complex interplay of lipid, protein and possibly carbohydrate mediators. Although a large variety of mediators have been implicated in the development of sepsis syndrome, a rapidly growing body of experimental evidence suggests that proteins belonging to the cytokine family are decisive factors in determining the pathobiology of sepsis syndrome. This article reviews recent information which demonstrates the role of cytokines in the development of sepsis syndrome. Since cytokines play critical roles in the initiation and perpetuation of sepsis syndrome, we also review interventions which abrogate the actions of cytokines and might be effective treatments for sepsis syndrome and related disorders.

Sepsis syndrome

A consensus conference of the American College of Chest Physicians/Society of Critical Care Medicine in 1991 proposed standardized terminology to define various aspects of sepsis syndrome [2]. These definitions stress the concept that the development of sepsis syndrome is related to a systemic inflammatory host response to an inciting event. The Consensus Conference recommended systemic inflammatory response syndrome (SIRS) as an umbrella term. SIRS is recognized by a constellation of cardinal signs which include tachypnoea, fever or hypothermia, tachycardia and leucocytosis or leucopenia with a "left shifted" differential white blood cell count. SIRS can result from either infectious or non-infectious conditions. Non-infectious conditions which are associated with SIRS include trauma, burns, haemorrhagic or hypovolaemic shock and pancreatitis. Sepsis is defined as SIRS which results from infection, which can be bacterial, paracystic, protozoan or viral. Although most cases of sepsis are related to Gram-negative infections, full blown sepsis can result from Gram-positive infections.

The severity of sepsis is proportional to the intensity of the host response. Severe sepsis is defined as sepsis which is associated with specific or multiple organ dysfunction. Septic shock occurs when there is systemic hypotension that is associated with tissue hypoperfusion and anaerobic metabolism. This simple classification system has been shown to predict mortality in a stepwise manner with a mortality of SIRS of 7%, sepsis of 16%, severe sepsis of 20% and septic shock of 46% [45]. This stratification of sepsis syndrome appears to reflect a continuum of systemic inflammation with increasing inflammation being associated with worsening clinical severity.

Cytokine hypothesis

Cytokines are a group of small signalling proteins produced by a large variety of cells that are thought to be important for host defence, wound healing and other essential host functions. Although cytokines are important for these homeostatic functions, excessive production and release of cytokines initiate widespread tissue injury which can result in organ dysfunction. Sepsis syndrome seems to result from overwhelming systemic inflammation which is caused by excessive release of cytokines into the systemic circulation.

The recent development of precise molecular tools for identifying and measuring cytokines has led to rapid accumulation of data implicating cytokines in the pathobiology of sepsis syndrome. Four cytokines, tumour necrosis factor α (TNFα), interleukin 1β (IL-1β), interleukin 6 (IL-6) and interleukin 8 (IL-8) have been most strongly associated with sepsis syndrome. In human and experimental animal models of sepsis, cytokines are released in a sequential manner resulting in a "cytokine cascade". The cytokine cascade is initiated when a stimulus such as Gram-negative bacterial endotoxin induces production and secretion of early or "proximal" cytokines, which include TNFα and IL-1β. TNFα

and IL-1β appear to mediate most of the physiological disturbances which are characteristic of sepsis. Infusion of either TNFα or IL-1β results in a sepsis-like state and specific blockers of either TNFα or IL-1β abrogate some of the manifestations of experimental sepsis. Proximal cytokines, as well as endotoxin, stimulate the production of later or "distal" cytokines, such as IL-6 and IL-8. Although the role of distal cytokines in sepsis is incompletely defined, they seem to intensify and perpetuate the inflammatory response and might have a role in tissue repair. IL-6 is a pleiotrophic mediator whose actions include modulation of lymphocyte function, activation of coagulation and induction of hepatic acute phase protein synthesis. Interestingly, IL-6 may down-regulate TNFα and IL-1β production, which might be important in limiting the inflammatory reaction. IL-8 is a potent activator and chemoattractant for polymorphonuclear leucocytes and is thought to mediate neutrophilic tissue inflammation. It is possible that IL-8 mediates neutrophilic inflammation in the lungs and other organs and that this process leads to tissue damage and organ dysfunction.

Cytokines are not stored in intracellular compartments and are newly synthesized and released in response to inflammatory stimuli. This regulation occurs predominantly at the level of gene transcription with new expression of cytokine mRNA. Specific transcription regulating proteins (transcription factors) regulate cytokine gene transcription by binding to regulatory portions of cytokine genes, and activating or inhibiting transcription. Each cytokine has a variety of transcription factor binding domains in the promoter region of its gene which interact in complex ways to control cytokine gene transcription.

Much progress has been made in recent years in understanding the actions of individual transcription factors and unravelling the interactions of these factors in regulating transcription of specific genes. One transcription factor, nuclear factor κB (NF-κB), appears to play a central role in regulating the cytokine cascade. NF-κB is activated in many cell types by stimuli such as endotoxin, TNFα and IL-1β. NF-κB activation and promoter binding are crucial for transcription of many cytokines and related molecules, including TNFα, IL-1β, IL-6 and IL-8 [55]. Further characterizing the roles of NF-κB and other transcription factors will probably lead to better understanding of the process that initiates and regulates the cytokine cascade. Since NF-κB may be a pivotal point of regulation for the cytokine cascade, interventions to inhibit NF-κB activation could down-regulate systemic inflammation to a much greater extent than blocking the production or action of a single cytokine.

In addition to activating a pro-inflammatory cytokine cascade, inflammatory stimuli activate the production of specific cytokine neutralizing molecules and counter-inflammatory cytokines that can modify the host inflammatory response. Cytokine neutralizing molecules include soluble cytokine receptors and cytokine receptor antagonists. Cytokine receptors have an extracellular binding domain, a hydrophobic membrane anchoring domain and an intracellular signal transducing domain. Soluble cytokine receptors result from proteolytic cleavage of the extracellular binding domain which can be released into the circulation. Soluble cytokine receptors have been identified for both the p75 and p55 TNF receptor, the IL-1 receptor and the IL-6 receptor. Cytokine receptor antagonists are cytokine-like molecules that bind to cell surface receptors but do not initiate signal transduction. A receptor antagonist has been identified only for IL-1 (IL-1ra).

Paradoxically, soluble TNF receptor (sTNFR) and IL-1ra are released into the circulation in 10–100-fold excess compared with TNFα and IL-1β. Naturally released cytokine antagonists modulate the *in vitro* biological actions of the corresponding cytokines, but their function and importance in human sepsis are not well understood. In patients with sepsis syndrome, prognosis may be determined, at least in part, by the balance of cytokines and cytokine neutralizing molecules. In patients with non-lethal sepsis, both IL-1ra and soluble cytokine receptors may be shed into the circulation in sufficient concentrations to neutralize the quantities of cytokines produced. However, the concentrations of these inhibitors may be inadequate to prevent the deleterious effects of exaggerated pro-inflammatory cytokine release which occurs in lethal septic shock.

Cytokines have synergistic, overlapping and antagonist effects. Counter-inflammatory cytokines as well as pro-inflammatory cytokines are produced following activation of the cytokine cascade. One counter-inflammatory cytokine, interleukin 10 (IL-10), is released into the circulation in human sepsis and has been shown to block the production of TNFα, IL-1β and IL-8 *in vitro*. IL-10, like IL-6, might have a role in limiting the systemic inflammatory reaction by regulating pro-inflammatory cytokine gene expression. The clinical manifestations of sepsis syndrome are probably determined by a complex interaction between pro-inflammatory cytokines, counter-inflammatory cytokines and cytokine neutralizing molecules.

Proximal cytokines

TUMOUR NECROSIS FACTOR α (TNFα)

TNFα is a primary mediator of inflammation, and has been implicated in a large number of infectious and non-infectious inflammatory diseases [58]. TNFα is a 17-kDa protein produced primarily by mononuclear phagocytes, which has pleiotrophic effects on target cells. Infusion of recombinant TNFα into humans results in SIRS with fever, haemodynamic abnormalities, leucopenia, elevated liver enzymes and coagulopathy [8, 51, 53, 64]. TNFα is capable of causing end-organ dysfunction which occurs in severe sepsis. In studies using chronically awake instrumented sheep, TNFa infusion caused pulmonary hypertension, hypoxaemia, decreased lung compliance and increases in pulmonary microvascular permeability [30, 71]. In human and animal models of sepsis induced by injection of bacterial endotoxin, TNFα production is quickly activated and can be detected in plasma.

Michie and colleagues infused *Escherichia coli* endotoxin into healthy volunteers and found that TNFα concentrations increased significantly and peaked 1 h after the infusion [39]. Several other studies have confirmed the observation that peak concentrations of TNFα are detected 60–90 min after endotoxin infusion [6, 28, 60].

TNFα appears to have a significant role in coordinating the inflammatory response and activating the cytokine cascade. *In vitro*, TNFα is a potent inducer of other cytokines, including IL + 1β, IL-6 and IL-8. In baboons injected with *E. coli*, treatment with TNFα antibodies decreased the production of IL-1β, IL-6 and IL-8, in addition to reducing morbidity and mortality [17, 21, 29, 46, 63].

TNFα can be detected in the plasma of many patients with sepsis, and concentrations generally correlate with severity of illness and outcome. Endo and colleagues [18] showed that TNFα, IL-1β, IL-6 and interleukin 2 (IL-2) concentrations in plasma were higher in patients with septic shock compared with patients with sepsis alone or with other causes of shock. Waage and colleagues [70] reported that 10 of 11 patients who died of meningococcaemia had elevated serum TNFα concentrations, while only eight of 68 survivors had similar elevations. In contrast with these findings, some studies have failed to show that initial TNFα concentrations predict outcome. For example, Casey, Balk and Bone [7] reported that concentrations of TNFα, IL-1β, IL-6 and endotoxin in patients with sepsis were elevated compared with patients in an intensive care unit without sepsis, but TNFα concentration did not predict mortality independently. In this study, only 54% of patients with sepsis had detectable plasma TNFα concentrations.

Other studies have suggested that persistently elevated plasma TNFα concentrations portend a poor prognosis in patients with sepsis. Martin and colleagues [36] evaluated plasma concentrations of TNFα and IL-6 serially in 30 patients with septic shock. All patients had elevated plasma TNFα and IL-6 concentrations. Non-survivors had persistently higher TNFα concentrations than survivors, but no differences were noted in IL-6 concentrations. Pinsky and colleagues [43] reported that TNFα and IL-6 concentrations were higher in septic than non-septic shock, and that persistence of IL-6 and TNFα in serum rather than peak concentrations predicted a poor outcome in patients with shock.

Since TNFα can be induced rapidly by endotoxin, causes a septic-like state after infusion, can activate production of other mediators and is elevated in patients with clinical sepsis, it should be considered a central mediator of sepsis. Some of the disparity in clinical reports regarding the frequency of elevation of plasma TNFα in plasma of patients with sepsis and the ability of elevated plasma concentrations to predict outcome is related to the use of different assays (with different sensitivities) to detect TNFα concentrations. In addition, there is considerable variation in patient populations and timing of plasma TNFα measurements in these studies. Given these considerations, TNFα concentrations are usually elevated in patients with sepsis compared with other critically ill patients and these concentrations are higher in patients with septic shock; however, persistently elevated TNFα concentrations may be better predictors of outcome than single measurements.

INTERLEUKIN 1 (IL-1)

IL-1 is the term used for two related proteins, IL-1α and IL-1β. Both molecules activate the same IL-1 receptors and therefore share various biological activities. IL-1 is synthesized by mononuclear phagocytes, polymorphonuclear leucocytes and other cell types and affects a wide variety of tissues [16]. IL-1β is the predominant form of this mediator produced by endotoxin-stimulated human monocytes and detected in the plasma of septic animals. Both IL-1α and IL-1β mimic many of the biological activities of TNFα. Infusion of either form of IL-1 into humans causes fever, haemodynamic abnormalities, anorexia, malaise, arthralgia, headache and neutrophilia [16, 56]. IL-1β is increased in humans after infusion of endotoxin, although at lower concentrations than TNFα [6, 28]. Like TNFα, IL-1β activates the production of other cytokines, including IL-6, IL-8 and TNFα. Further evidence of a primary role of IL-1β in sepsis syndrome is provided by studies using IL-1ra to block the biological activity of exogenous and endogenous IL-1β [15]. For example, prior treatment with IL-1ra decreased the mortality of rabbits treated with endotoxin [42]. In addition, Fischer and colleagues [20] reported that IL-1ra treatment reduced the production of IL-1, IL-6 and IL-8 (but not TNFα), and improved survival after *E. coli* infusion in baboons.

IL-1β is not normally present in human plasma, but has been detected in the plasma of patients with sepsis. McAllister and colleagues [38] reported cytokine measurements from three patients who developed sepsis after being transfused with packed erythrocytes contaminated with Gram-negative bacteria. These patients had detectable IL-1β that peaked by 4 h and subsequently returned to normal in the two survivors, but remained elevated in the non-surviving patient for 22 h. Plasma IL-1β can be detected in a minority of patients with sepsis but seems to be a measure of the severity of sepsis. Endo and colleagues [18] found that plasma IL-1β was elevated in only two of 40 patients with sepsis alone, but 15 of 22 patients with septic shock had elevated IL-1β concentrations. Casey, Balk and Bone [7] reported that 37% of patients with sepsis had initially detectable plasma concentrations of IL-1β, that the mean IL-1β concentration was higher in patients with sepsis than critically ill patients without sepsis and that the initial IL-1 plasma concentration did not predict mortality in patients with sepsis. A recent study by Goldie and colleagues [24] detected IL-1β in plasma of 29% of 146 patients with severe sepsis but no correlation with mortality was found. Taken together, the available studies of IL-1β in human sepsis show that IL-1β is elevated in plasma of some patients with sepsis. Initial plasma IL-1β concentration may correlate with severity of sepsis, but no convincing independent association with mortality has been found.

Distal cytokines

IL-6

IL-6 is a 21-kDa glycoprotein produced by many cell types, including lymphocytes, fibroblasts and monocytes. IL-6 has a variety of biological effects, including activation of B- and T-lymphocytes, induction of acute phase protein production in the liver, and modulation of haematopoiesis [4]. In addition, IL-6 can activate the coagulation system [65] and function as a pyrogen [14]. *In vitro*, IL-6 suppresses the production of TNFα and IL-1β [1, 48]. The exact role of IL-6 in sepsis is uncertain. Infusion of IL-6 into experimental animals does not result in a sepsis-like state [44]. Xing and colleagues [72] transfected the IL-6 gene into rat lung tissue and found that expression of IL-6 resulted in lung lymphoid hyperplasia and acute phase protein production by the liver, without any other untoward effects.

Experimental injections of endotoxin or bacteria result in detectable plasma IL-6, with peak concentrations occurring subsequent to peak TNFα and IL-1 concentrations. After i.v. endotoxin injection into healthy human volunteers, Kuhns, Alvord and Gallin [32] found that plasma TNFα peaked at 1.5–2 h, whereas IL-6 peaked at 4 h. In baboons treated with sublethal doses of endotoxin or *E. coli*, plasma TNFα concentrations peak at 1–2 h, followed by IL-6 at approximately 3 h [11, 68]. In these same studies, lethal doses of *E. coli* caused peak plasma concentrations of TNFα at 2–3 h and peak IL-1β concentrations at 3–5 h, but IL-6 concentrations were still increasing 6–8 h after injection.

The appearance of plasma IL-6 in sepsis may be related directly to TNFα and IL-1 production. In mice, IL-1 and TNFα synergize to increase IL-6 production, and the production of IL-6 after endotoxin injection can be inhibited by prior treatment with anti-TNFα antibodies [52]. In addition, TNFα antibodies and IL-1ra attenuate IL-6 production in bacteraemic baboons [20, 21].

Although IL-6 is an integral part of the cytokine cascade, its individual role in the pathobiology of sepsis is unclear. In experimental animals, IL-6 blockade has not resulted in consistent benefit. Libert and colleagues [33] showed anti-IL-6 antibodies and antibodies to the IL-6 receptor offered some protection against lethal doses of TNFα in mice, but this protection could be overcome with higher doses of TNFα. In chimpanzees treated with endotoxin, monoclonal anti-IL-6 antibodies did not affect plasma TNFα concentrations, IL-8 concentrations, neutrophilic leucocytosis or neutrophil degranulation [65]. The major effect of anti-IL-6 antibody treatment in this study was to attenuate endotoxin-induced activation of coagulation.

IL-6 concentrations correlate more closely than other cytokines with severity and outcome of human sepsis, despite the fact that the role of IL-6 in this syndrome is not well defined. Plasma IL-6 may simply be a marker for activation of the cytokine cascade, and thus may reflect the association of host inflammatory response and disease severity. Hack and colleagues [26] reported that 32 of 37 patients admitted to an intensive care unit with sepsis had elevated IL-6 concentrations. IL-6 concentrations were higher in patients with septic shock, and IL-6 concentrations correlated with mortality. Damas and colleagues [12] reported serial measurements of TNFα and IL-6 in 40 patients with sepsis. In this study, peak serum IL-6 concentrations correlated with peak TNFα concentrations, APACHE II scores, and increased mortality. Several other studies [5, 7, 18, 24, 61] have confirmed this relation between IL-6 concentrations and the severity and outcome of sepsis. In addition, Moscovitz and colleagues [41] reported that in 100 patients admitted as emergencies and suspected of having bacteraemia, plasma IL-6 concentrations predicted bacteraemia and subsequent death from infection. IL-6 plasma concentration may also reflect severity of other diseases such as alcoholic hepatitis [54]. Based on the available information on IL-6 in human disease, plasma IL-6 concentration in sepsis appears to be a good indicator of activation of the cytokine cascade and predicts subsequent organ system dysfunction and death.

IL-8

IL-8 is a small, basic protein which belongs to the chemokine gene family of cytokines. IL-8 is produced by mononuclear phagocytes, polymorphonuclear leucocytes, endothelial cells, epithelial cells and a variety of mesothelial cell types in response to various stimuli, including endotoxin, IL-1 and TNFα. The primary function of IL-8 is to activate and chemoattract neutrophils to sites of inflammation. In addition, basophils and T-lymphocytes are attracted by nanomolar concentrations of IL-8, and IL-8 has been implicated an angiogenic factor [31].

When injected intradermally into humans, IL-8 induces a time-dependent perivascular neutrophil influx [62]. I.v. injection of IL-8 into baboons causes no haemodynamic abnormalities and no detectable production of TNFα, IL-1β or IL-6 [69]. Transient granulocytopenia followed by granulocytosis occurs, but no significant tissue neutrophilic inflammation or injury. In human and primate models of sepsis, plasma IL-8 levels are detectable following endotoxaemia, and the kinetics mirror IL-6 plasma concentrations [32, 68]. In baboons, plasma IL-8 peaks after 2.5–3 h after a sublethal dose of endotoxin, whereas TNFα concentrations peak at 1 to 2 h [68]. Like IL-6, IL-8 production in sepsis appears to be activated by TNFα. Redl and colleagues [46] showed that treatment of baboons with anti-TNFα antibodies before *E. coli* infusion results in significantly decreased plasma IL-8 concentrations. In human sepsis, Marty and colleagues [37] and Hack and colleagues [27] have reported that plasma IL-8 concentrations are elevated in patients with sepsis and that higher concentrations correlate with mortality.

IL-8 may be important in mediating some of the organ dysfunction, including adult respiratory distress syndrome (ARDS), that occurs as a consequence of sepsis syndrome. IL-8 is present in bronchoalveolar lavage (BAL) fluid of patients with ARDS. BAL IL-8 concentration correlates with BAL neutrophil count and increased mortality in patients with ARDS [9, 40]. In a rabbit ischaemia-reperfusion lung injury model, where tissue injury is mediated at least partially by neutrophils (similar to ARDS), anti-IL-8 antibodies have been shown to have a protective effect [50]. Taken together, these data indicate that the function of IL-8 in sepsis is likely to be recruitment and activation of neutrophils in specific sites which can lead to tissue injury.

Soluble receptors and receptor antagonists

SOLUBLE CYTOKINE RECEPTORS

Soluble cytokine receptors have been described for TNFα, IL-1β and IL-6. Currently, the greatest amount of information regarding soluble cytokine receptors in sepsis syndrome examines the role of soluble TNFα receptors (sTNFR) [10]. Almost no data exist which define the role of the sIL-1R, sIL-6R or other soluble receptors in human sepsis syndrome. Soluble receptors have been described for both the p75 (sTNFR-p75) and p55 TNF (sTNFR-p55) receptor (also called the type I or type A and type II or type B TNFR, respectively). These soluble receptors are produced apparently by proteolytic cleavage of the extracellular binding domain of the TNF receptors from the cell surface. Since these sTNFR retain the ability to bind TNFα, they can modulate the actions of this cytokine. The proportion of free TNFα and TNFα bound to sTNFR exists in equilibrium and this balance may determine the bioactivity of a given TNFα concentration.

Plasma sTNFR concentrations are present in normal humans and are released in excessive amounts into the circulation in response to endotoxaemia. In healthy human volunteers, endotoxin injection results in a 4–5-fold increase in sTNFR concentration by 3 h, with peak plasma concentrations 10 times that of TNFα [57]. Van Zee and colleagues [67] showed that the kinetics of TNFα production and sTNFR shedding are different in experimental models of sepsis. In these experiments, plasma TNFα concentration peaked 1 h after endotoxin infusion, but plasma sTNFR concentration peaked at 3 h. In human sepsis, sTNFR is increased and correlates with severity of illness and mortality. Ertel and colleagues [19] reported that plasma concentrations of both species of sTNFR were increased in patients with sepsis and correlated with APACHE II score, multiple organ failure score and mortality. These findings were supported by Goldie and colleagues [24] who found that higher plasma sTNFR concentrations predicted mortality in a group of patients with severe sepsis.

The role of sTNFR in sepsis is incompletely understood, as is the relation between elevated plasma sTNFR and increased mortality. Plasma sTNFR concentrations may simply be a marker for the exaggerated inflammatory state and not reflective of TNFα/sTNFR ratios in certain tissues or at critical times. Alternatively, the TNFα-sTNFR complex may serve as a slow release reservoir of TNFα, which could perpetuate the inflammatory response.

IL-1 RECEPTOR ANTAGONIST (IL-1RA)

IL-1ra was first identified as a 23 kDa protein purified from the urine of patients with monocytic leukaemia [49]. The amino acid sequence for this protein is 26% homologous to IL-1β and 19% homologous to IL-1α. IL-1ra blocks IL-1 activity by competing for binding to type 1 and type 2 IL-1 receptors without causing signal transduction [16]. IL-1ra can attenuate endotoxin effects in animal models of sepsis [20, 42]. In human volunteers, plasma IL-1ra concentrations are increased after endotoxin injection, with peak concentrations at 3–4 h [32]. In humans with sepsis, IL-1ra is present in plasma at markedly higher concentrations than IL-1, but its function in this setting is uncertain. Gardlund and colleagues [22] reported that 11 of 13 patients with septic shock had plasma IL-1ra/IL-1β ratios > 2000. van Deuren and colleagues [66] found significantly higher plasma IL-1ra concentrations in patients with meningococcaemia and shock than in patients with meningococcal meningitis alone. Goldie and colleagues [24] reported that plasma IL-1ra concentrations were elevated in patients with severe sepsis, but concentrations did not correlate with outcome in this group of patients.

Counter-inflammatory cytokines

IL-10

In addition to pro-inflammatory cytokines, cytokines with predominantly counter-inflammatory actions have been identified. IL-10 was first described as a product of TH2 lymphocytes that inhibits cytokine production by activated macrophages. *In vitro,* IL-10 can inhibit production of TNFα, IL-1, IL-6 and IL-8 [35]. Gerard and colleagues [23] showed that treatment of mice with IL-10 before endotoxin could prevent endotoxin-induced mortality and diminish plasma TNFα release. Additionally, Rogy and colleagues [47] demonstrated that transfecting mice with the human IL-10 gene resulted in transgene expression in the animals, and that these animals were protected from lethal doses of endotoxin. Finally, treatment of mice with anti-IL-10 antibodies has been shown to increase endotoxin-induced TNFα release and worsen mortality [35].

Recent human studies have shown that IL-10 is detectable in plasma of patients with sepsis [13, 25, 34, 66]. van Deuren and colleagues [66] found significantly higher plasma IL-10 concentrations in patients with septic shock compared with patients without shock. This finding was corroborated by Marchant and colleagues [34], who reported that higher IL-10 concentrations were present in patients with septic shock than in patients with sepsis alone. The importance of IL-10 in human sepsis is currently uncertain.

Anticytokine treatment strategies

With increasing evidence that activation of the cytokine cascade is of critical importance in determining the pathobiology of sepsis, there has been increasing enthusiasm for treatments to interrupt this cascade. Current human trials utilizing anticytokine treatments for sepsis have been reviewed recently by Suffredini [59]. Three anticytokine treatment strategies have been evaluated in humans with sepsis: (1) blocking endotoxin effects with polyclonal or monoclonal endotoxin antibodies, (2) blocking TNFα effects with anti-TNFα antibodies or with TNF receptor constructs, and (3) blocking the actions of IL-1 with IL-1ra.

To date, human trials of anticytokine therapy have been relatively disappointing with regard to identifying treatments to improve survival in sepsis. The reason for this lack of efficacy is unclear. Certainly the timing and dose of these interventions may be critical, since these treatments affect proximal steps in the cytokine cascade. Once the cascade is activated, interventions to decrease proximal cytokine actions may be insufficient to improve outcome significantly. In addition, cytokines have redundant and overlapping functions so that blocking the production or action of single cytokines may not affect outcome. Finally, blocking cytokine production may inhibit host defence functions that are critical for recovery from sepsis. There may be a balance between excessive inflammation which causes tissue injury and inadequate inflammatory response which compromises host defence functions.

Therapies designed to modulate activation of the cytokine cascade are certainly attractive and may eventually prove beneficial in sepsis. A better approach than current treatment strategies may be to modulate the cytokine cascade by targeting elements that control production of both proximal and distal cytokines, such as the transcription factor NK-κB. Counter-inflammatory molecules such as IL-10 may also be capable of globally modifying the cytokine cascade. Regardless of the therapeutic approach, future studies for the treatment of sepsis should be conducted as prospective, randomized placebo-controlled, multi-centre clinical trials [3]. These trials will require close cooperation between basic scientists, clinicians and pharmaceutical companies.

Summary

Sepsis is a constellation of clinical signs and symptoms resulting from excessive systemic host inflammatory response to infection. This inflammatory response is largely mediated by cytokines, which are released into the systemic circulation. Plasma concentrations of specific cytokines, TNFα, IL-1β, IL-6 and IL-8 are frequently elevated in human sepsis and cytokine concentrations correlate with severity and outcome of sepsis. In addition to pro-inflammatory cytokines, soluble cytokine receptors, cytokine receptor antagonists and counter-inflammatory cytokines are also produced in large quantities in patients with sepsis; however, the specific role of these molecules in sepsis remains undefined. A complex interaction of cytokines and cytokine-neutralizing molecules probably determines the clinical presentation and course of sepsis. Intervening in this sequence of events to modify the host inflammatory responses may prove to be a beneficial treatment strategy for sepsis, but currently tested anticytokine therapies have been largely unsuccessful.

Nutrition and immunonutrition

M. J. O'LEARY AND J. H. COAKLEY

Nosocomial infections are common in critically ill patients and frequently lead to multiple organ failure and death. Such patients may be vulnerable to infection because of deficiency in immune function brought about by severe illness [32, 54, 66]. Requirement for prolonged ventilation is associated with the development of nosocomial pneumonias and sepsis, and the development of weakness and wasting of skeletal and respiratory muscles is a major cause of prolonged weaning from ventilatory support despite resolution of the underlying condition [15]. It is now recognized that nutritional support has a crucial role in maintaining immunological function and in the prevention of muscle wasting during critical illness. Failure to address the issues of muscle wasting and weakness in critical illness leads to delays in mobilization and prolongation of time to recovery [14, 15].

In this article we review recent work which has highlighted the potential importance of the route of administration, the use of specific nutrient substrates and the use of adjuncts to nutrition such as anabolic hormones in maintaining or augmenting immunological function and preventing muscle catabolism in critically ill patients. Nutritional support is a vital component of all preventive therapies available for multiple organ failure in critical illness.

Weight loss and wasting in critical illness

Despite good evidence that nutritional support in certain circumstances leads to reductions in morbidity and mortality [82], increased utilization of nutritional support has unfortunately led to little change in the rapid development of muscle wasting and consequent weakness associated with critical illness. This is important because it has been shown that the degree of weight loss occurring during acute illness is correlated with mortality [20]. Cachexia in critical illness may be explained by the combined effects of malnutrition, immobilization and the hypercatabolic state which occurs after stress, trauma and sepsis. Many patients in the intensive care unit (ICU) are malnourished on admission because of anorexia as the result of illness or fasting in preparation for surgery and this may be exacerbated by delays in commencing nutritional support after ICU admission.

Even hyperalimentation, however, fails to reverse muscle wasting and negative nitrogen balance during critical illness because the metabolic responses to uncomplicated starvation and to stress, trauma and sepsis are quite different. In starvation there is a fall in basal metabolic rate, resting energy expenditure and tissue oxygen consumption. Hepatic glycogen stores are sufficient for 24 h of glycogenolysis and after this a decrease in insulin secretion and increase in glucagon results in lipolysis and hepatic gluconeogenesis. There is then an adaptive phase during which gluconeogenesis falls and ketosis increases, with ketone bodies becoming the fuel for otherwise glucose-dependent tissues. In uncomplicated starvation, therefore, lean body mass is generally preserved until late, fat breakdown being the chief source of calories. The administration of sufficient nutrition will thus convert the starved catabolic patient to an anabolic state.

After stress, trauma or sepsis, however, the hypermetabolic state seen is distinct from that which follows simple starvation and in particular the adaptation to fat metabolism does not occur. There is a significant increase in caloric requirements, with increases in basal metabolic rate and tissue oxygen consumption and consequent negative energy balance. The circulating concentrations of many hormones (for example catecholamines, glucagon, cortisol and growth hormone) and cytokines are increased leading to rapid glycogenolysis, increased hepatic gluconeogenesis and a reduction in lipolysis. The ability to use glucose and fat is impaired and consequently there is an increased dependency on muscle breakdown for fuel. There is weight loss and muscle wasting which leads to an increased loss of nitrogen in the urine. Most of this nitrogen loss originates from muscle proteins because of increases in both whole body protein breakdown and synthesis [75, 80], with breakdown predominating over synthesis [3]. Weight loss of 30 % was common in burns patients before the introduction of routine nutritional support [94]. In sepsis proteolysis can cause nitrogen losses of up to 30 g (represents as much as 800 g muscle mass [52]) per day. Reversal of muscle wasting and negative nitrogen balance in these patients requires control of the effectors of hypermetabolism together with adequate nutritional support. Muscle loss is not prevented by hyperalimentation, however, this leading instead to hepatic steatosis, abnormal liver function and excess carbon

(*Br. J. Anaesth.* 1996; **77**: 118–127)

Key words

Nutrition. Muscle skeletal, wasting. Infection, nosocomial. Immune response, suppression.

M. J. O'LEARY, FRCA, J. H. COAKLEY, MD, MRCP, Intensive Care Unit, St Bartholomew's Hospital, West Smithfield, London EC1A 7BE.

dioxide production which some authors believe may be detrimental to weaning from ventilatory support [24]. Over the past 20 years the energy intake prescribed to critically ill patients receiving parenteral nutrition has fallen, and it appears that the energy requirements of these patients are in fact similar to those of normal healthy subjects [24]. Energy requirements during critical illness have been overestimated in the past because measurements of resting energy expenditure were made at times of peak hypermetabolism and then extrapolated to longer periods, the effect of infused nutrients at time of measurement was not considered, and corrections for pyrexia were made inappropriately [23]. The lower energy requirements of these patients still reflect hypermetabolism, however, but this is balanced by the effects of reduced physical activity. It has now become clear that it is the quality rather than the quantity of nutrients provided that is of most importance in preventing muscle loss and supporting essential body systems such as the immune system during critical illness. In particular, the amino acid glutamine has been recognized to be of importance to muscles, the gut and to the immune system.

Nutritional assessment

A number of variables can be measured to assess a patient's nutritional status. These include serum concentrations of albumin and transferrin, the triceps skinfold thickness and the cutaneous responses to recall antigens [27]. In practice, however, these measurements are relatively insensitive when used for individual patients, and malnourished patients are generally accurately identifiable on the basis of a subjective clinical assessment [20].

Although it is possible to estimate energy requirements using standard equations such as the Harris-Benedict equation or by indirect calorimetry, these measurements are rarely required in the clinical setting. The majority of ICU patients require 25–30 kcal kg^{-1} day^{-1}. Energy intake greater than this may result in complications associated with overfeeding, except in certain situations such as after severe burns, where greater quantities may be required. Protein requirements for catabolic patients are 1.2–2.0 g kg^{-1} day^{-1} if renal function is normal. Additional supplementation does not result in increased protein synthesis and may contribute to uraemia. Protein dose may need alteration in light of changes in renal and hepatic function, as many catabolic patients are unable to utilize administered nutrients efficiently until they are in a recovery phase. A non-protein calorie to nitrogen ratio of between 100:1 and 150:1 must be administered to permit utilization of the protein load for protein synthesis. For patients requiring parenteral feeding it is recommended that dextrose should provide 70–80% of non-protein energy and lipid the rest, despite the concerns about the immunosuppressive effects of lipid emulsions discussed below [43, 73].

Many critically ill patients require fluid restriction as a therapeutic approach, but will often be given large fluid volumes including antibiotics, vasopressors and other drug infusions. One of the problems encountered in administering nutritional support during critical illness is allowing adequate volume to deliver sufficient quantities of energy and protein. In many cases a balance has to be accepted between the desired nutritional intake and the volume space available.

Route of nutrition in critical illness: enteral *vs* parenteral

Along with the move away from hyperalimentation in critical illness, there has been a change in emphasis from parenteral to enteral administration of nutrients. This has been driven by increased understanding of the pathology of nosocomial infections in the critically ill and the role of the gut in their development. Infection is the most common cause of mortality in critically ill patients irrespective of the underlying cause of their critical illness. The development of nosocomial pneumonia is associated with a mortality exceeding 30% [57]. Interest has centred on the gut as a reservoir of bacteria and endotoxin which may be the cause of nosocomial infections and sepsis syndrome [59]. Tracheal and nasogastric intubation, the use of H_2-receptor antagonists as stress ulcer prophylaxis and the cessation of enteral nutrition all predispose to bacterial overgrowth in the upper gastrointestinal tract. It has been demonstrated that bacteria can be isolated from the stomach of critically ill patients some days before their appearance in the tracheal aspirate [5]. Furthermore, gut mucosal atrophy occurs in the absence of enteral feeding because enterocytes normally obtain some of their nutrients directly from the intestinal lumen. Mucosal atrophy may allow translocation of bacteria or endotoxin to the portal circulation. Translocation of bacteria and endotoxin has been shown to occur in animal models of critical illness [96], but has as yet not been convincingly demonstrated to occur in humans. Circumstantial evidence in support of translocation occurring in humans is provided by the demonstration of increased gut permeability after trauma [50], burns [100] and in critical illness [34, 37], and the finding of significant amounts of endotoxin present in the peritoneal cavity and bacteria present within organ specimens from organ donors without intra-abdominal injuries [90]. Interestingly, 95% of the organ donors in this latter study received no feeding. The use of total parenteral nutrition (TPN) is also associated with atrophy of gut-associated lymphoid tissue (GALT) [51]. The translocation of bacteria into the circulation may stimulate macrophages to release cytokines which generate the hypermetabolic response seen in sepsis, and may be responsible for producing hypoxia and multiple organ failure [12].

In addition to these concerns about the inadvisability of substituting TPN for enteral feeds has come evidence that TPN itself has deleterious immunological effects. TPN appears to accentuate the metabolic response to stress, trauma and sepsis by increased pro-inflammatory cytokine and stress hormone release, by the effects of hyperglycaemia and by a specific immunosuppressive effect of lipid emulsions [73]. Omega-6 polyunsaturated fatty acids

(PUFAs) are the form found in Intralipid used in TPN and may have significant immunosuppressive effects, mainly through stimulation of production of prostaglandin E_2. Prostaglandin E_2 has a direct suppressant effect on delayed cell-mediated immunity, suppresses complement synthesis, increases the generation of superoxide radicals and increases suppressor T-cell activity. In addition, omega-6 PUFAs cause increased production of thromboxane A_2 which results in vasoconstriction and thrombosis [1]. TPN also depresses pulmonary macrophage function [81], and depresses local and systemic immune responses to intraperitoneal infection [28, 43]. The use of TPN has been shown to increase the incidence of intra-abdominal abscesses and septic complications after pancreatic resection for malignancy [8], and to increase mortality three-fold in burns patients [38]. In the clinical situation, however, it is likely that the major adverse immunological effect of TPN is due to the cessation of enteral feeding with the consequent development of mucosal atrophy and bacterial overgrowth.

Animal studies have demonstrated that continuous tube feeding started immediately after burn injury reduces the post-burn hypermetabolic response, and prevents the gut mucosal atrophy seen in a comparative delayed enteral feeding group [64]. Enteral feeding resulted in fewer septic complications in high-risk surgical patients [65] and after abdominal trauma [47]. Enteral nutrition has been shown to prevent bacterial and endotoxin translocation in experimental animal models [96], and a recent study in humans has demonstrated a significant decrease in gut mucosal permeability occurring in critically ill patients receiving glutamine supplemented enteral nutrition when compared with a group receiving standard TPN [34].

In addition to providing the mucosa with essential nutrients and preventing the development of mucosal atrophy, the provision of enteral nutrition may also increase gut blood flow. Reduction of oxygen and nutrient delivery to the gut mucosa because of microcirculatory disturbances is thought to be common in sepsis, and may also play a part in the breakdown of the mucosal barrier to bacteria and endotoxins. Enteral feeding has been shown to ameliorate the decrease in splanchnic blood flow associated with the institution of positive end-expiratory pressure ventilation for acute lung injury [74]. This effect may occur even with only small volumes of feed. Enteral feeding also results in improved hepatic synthesis of albumin compared with parenteral nutrition [19].

For a significant benefit to be seen from the use of enteral rather than parenteral feeding the enteral feed must be started as soon as possible after the insult. No difference in infectious complications were seen in head injury patients begun on enteral feeds 5 to 7 days after injury when compared with a group who were given early TPN; however, if the enteral feed was commenced within 3 days of the injury infectious complications were significantly reduced [48]. It is now generally accepted that enteral feeding can be started almost immediately after operation even in patients undergoing abdominal surgery, and in critically ill patients who are sedated, paralysed and ventilated on the ICU. Gastric stasis may be a problem, but this can be overcome by the use of prokinetic agents, nasojejunal tubes or feeding enterostomies.

It is often not possible to achieve comparable energy delivery by the enteral route to that which can be obtained by TPN; however, although TPN guarantees a certain nutrient delivery utilization may be incomplete. TPN will be required in those patients in whom enteral feeding is contraindicated or fails because of malabsorption, ileus or intractable diarrhoea. Supplemental parenteral nutrition may be needed when it is not possible to provide adequate energy enterally. It is likely, however, that if even small amounts of nutrients can be given enterally this will help maintain mucosal integrity, prevent bacterial overgrowth and help maintain splanchnic blood flow.

There is much interest in alterations in the composition of TPN solutions in an attempt to ameliorate some of the adverse effects associated with their use. Glutamine is a non-essential amino acid with poor stability in solution so is not normally included in parenteral feeds. However, in times of physiological stress blood glutamine concentrations decrease and the amino acid may become "conditionally essential". Glutamine is an important nutrient for enterocytes, and parenteral nutrition containing glutamine has been shown to maintain intestinal barrier function in patients with inflammatory bowel disease [89], and maintain intestinal absorptive capacity in a small group of critically ill patients [88]. There is as yet no clinical evidence that glutamine-supplemented TPN reduces morbidity and mortality caused by infection in critical illness however. The molecular mechanism underlying the beneficial effect of glutamine on gut mucosa is not known, but glutamine has been shown to augment heat shock protein messenger RNA and protein expression in rat enteric crypt cells after injury *in vitro* [22]. Heat shock proteins are stress-response genes that protect cells from various injuries. *Escherichia coli* sepsis in rats causes selective damage to enteric crypt cells, and the morphological abnormalities seen can be partially prevented by parenteral administration of glutamine [95]. In health, gut mucosal cells derive glutamine from luminal contents [84]. If enteral nutrition is better than TPN because of its effects on the gut, and addition of glutamine to TPN offsets some of its deleterious effects on the gut, it is tempting to extrapolate this to recommend the inclusion of glutamine in enteral nutrition for critically ill patients. There are as yet, however, no published studies demonstrating increased efficacy of glutamine-enriched enteral nutrition over standard formulas in reducing infectious complications in the heterogeneous intensive care population.

Preventing muscle loss

GLUTAMINE

Protein loss from muscle during critical illness may occur in response to depletion of plasma amino acids (increased demand), or alternatively increased muscle protein turnover may be stimulated by circulating mediators (hormones or cytokines). The loss of muscle protein may have short-term advantages such as providing substrate for the manufacture of acute phase proteins and fuel for more essential body processes. This may include provision of amino acids such as glutamine for protein synthesis within the cells of the immune system and intestine, for repair processes and for hepatic gluconeogenesis. However, consequential plasma glutamine depletion may be central to the failure of traditional nutritional regimes to reverse muscle catabolism in critical illness. Glutamine constitutes 60% of free intracellular amino acids in skeletal muscle [77]. It is the most important carrier of ammonia from the peripheral tissues to the splanchnic area, and serves as an oxidation fuel during cell division [83]. It is also a donor of nitrogen for DNA and RNA synthesis and hence is essential for the proliferation of cells [79]. Glutamine is the principal metabolic fuel of gut mucosal cells [61, 85], lymphocytes and monocytes [2, 7]. Glutamine also has important roles in generation of ammonia by the kidney and in gluconeogenesis in the liver. Lung, adipose tissue and the liver are all sources of glutamine, but skeletal muscle is thought to be the major site of glutamine storage, synthesis and release. Animal and human studies have demonstrated a net flux of glutamine from peripheral to splanchnic tissue with increased hepatic and intestinal uptake after operative stress or in sepsis [21, 83]. In illness glutamine requirements increase markedly [4], and utilization may exceed endogenous production.

If adequate dietary glutamine is not provided net catabolism of skeletal muscle will occur to supply the requirements of glutamine-dependent tissue. Plasma and muscle glutamine concentrations decrease in catabolic states [4, 70, 77]. In patients with sepsis, depleted muscle glutamine was associated with increased concentrations of glutamine precursors [77]. It is therefore suggested that muscle glutamine depletion in illness may be due to both reduced intracellular synthesis and increased efflux to supply glutamine dependent tissues. A positive correlation between glutamine concentration and rate of protein synthesis has been demonstrated in perfused rat skeletal muscle [41, 55], and protein breakdown was inhibited by glutamine in the same model [55]. Recent studies in humans have suggested that addition of glutamine to nutritional regimes may restore depleted plasma and muscle concentrations and improve nitrogen balance in patients with sepsis [77], after bone marrow transplant [101] and after surgery [86]. In addition, the reduction in muscle protein synthesis seen after operation (as assessed by ribosome analysis) was counteracted [36]. Traditionally, glutamine has not been included in parenteral or enteral feeds for critically ill patients because of difficulties with solubility and stability. Heat sterilization causes glutamine to break down to ammonia and pyroglutamic acid. Recent work has demonstrated that degradation is minimized with cold sterilization; however, solubility problems persist. Glutamine in parenteral nutrition requires large volumes which may not be practical for use in critically ill patients. This problem may eventually be overcome by the use of glutamine dipeptides which are soluble in smaller volumes. Until these issues are resolved the addition of glutamine to parenteral nutrition remains essentially a subject for further research.

There are available, however, proprietary preparations of enteral feeds containing glutamine. Unfortunately, there is little work yet published on the efficacy of glutamine-enriched nutrition in heterogeneous groups of critically ill patients. Preliminary results from a randomized study of glutamine-enriched parenteral nutrition in critical illness have been reported [33]. Plasma glutamine concentrations taken before feeding were significantly depressed in both study and control groups in comparison with normal volunteers. Glutamine-enriched feeding (TPN including 25 g glutamine a day) resulted in partial restoration of plasma concentrations towards normal on day 5, significantly different from the control group. Muscle glutamine concentrations were severely depressed in all patients undergoing muscle biopsies before feeding; however, 5 days of glutamine-enriched feeding did not affect muscle glutamine concentrations when compared with the control feeding group. There is still some debate as to the optimum daily amount of glutamine needed to maintain plasma and muscle concentrations during critical illness. Most workers have used 25 g a day, however, Zeigler has reported a series of dose-response studies conducted to evaluate the clinical safety, efficacy and metabolic effect of glutamine-enriched feeding in humans [98]. Glutamine was administered orally and parenterally in two doses (0.285 g kg^{-1} day^{-1} (approximately 20 g day^{-1}) and at 0.57 g kg^{-1} day^{-1} (approximately 40 g day)) to normal volunteers and to patients after bone marrow transplant (parenteral only). In the patient study plasma glutamine decreased from pretreatment concentrations in both control and low-dose glutamine groups over the first 2 weeks, whereas plasma glutamine increased in the high dose group. Muscle glutamine was not studied; however, nitrogen retention was enhanced in the high dose group, there being no difference between the low dose group and control group. It may be that a higher dose of glutamine is required to restore plasma and muscle glutamine concentrations in the critically ill, and the results of further studies are awaited.

It is interesting to note that normally little dietary glutamine reaches the circulation as a substantial amount is utilized by intestinal cells. Consequently, although there are theoretical reasons to believe that glutamine-enriched enteral nutrition may be the optimum nutritional regime to protect the gut in critical illness, it may not be possible to deliver sufficient glutamine via the enteral route to obtain beneficial effects on muscle catabolism or immune function.

OTHER NUTRIENTS AND GROWTH FACTORS

Some other amino acids which, in certain situations may become essential, are also deficient or absent from parenteral nutrition solutions because of their poor stability. These include cysteine and tyrosine. In some patients with liver disease, the hepatic conversion of phenylalanine to tyrosine and methionine to cysteine is inadequate, and unless sufficient cysteine and tyrosine are included in the nutritional regime wasting of lean tissue will occur [78].

The availability of human anabolic hormones synthesized by recombinant techniques has raised interest in their use in the amelioration or prevention of muscle catabolism during critical illness. It has been postulated that derangement of the growth hormone/insulin-like growth factor 1 (IGF-1) axis may partly explain muscle loss and negative nitrogen balance in critical illness. Growth hormone has both direct fuel regulating effects (lipolysis and insulin antagonism) and indirect growth promoting actions (anabolism) which influence amino acid uptake and protein synthesis. Its anabolic actions are mediated through IGF-1, which is secreted principally by cells of the liver under the control of growth hormone, although synthesis may occur in many other tissues. Critically ill patients are relatively resistant to growth hormone, and circulating concentrations of IGF-1 are reduced despite increased basal secretion of growth hormone [76]. Studies of the therapeutic use of growth hormone in seriously ill humans have mainly involved those with burns [102], although recently there have been reports of the use of growth hormone after surgery [62, 63], sepsis [91] and pancreatitis [99]. These studies confirm that a positive nitrogen balance can be promoted, even in the presence of hypocaloric nutrition [42, 58]. After operation protein synthesis is stimulated in patients, along with an increase in the concentration of free glutamine in muscle [35, 53]. It is possible that the effect of growth hormone therapy on muscle protein synthesis is related to preservation of muscle free glutamine concentrations [55]. It is unclear whether the preservation of muscle glutamine is due to decreased efflux from muscle, increased synthesis in muscle or repletion of the plasma pool by increased hepatic or pulmonary release of glutamine [93]. Growth hormone may also have direct effects on immunological function. In a study of daily s.c. injections of growth hormone (GH) after elective cholecystectomy fewer septic complications were reported in the GH group in comparison with placebo-treated controls [63]. Growth hormone administration to critically ill patients does not appear to be associated with any significant adverse effects, and a multicentre trial of its use in critical illness is currently in progress. IGF-1 has also been administered to patients after operation and to critically ill patients without adverse effects, but as yet there is insufficient information on its use therapeutically in these groups.

Nutrition and the immune system

It has long been recognized that immune function is depressed in seriously ill patients [32, 54, 66]. The metabolic response to stress, trauma and sepsis is closely interrelated with the immunological changes seen after such events. Consequently it has been proposed that nutritional support would be likely to improve host defence mechanisms and reduce morbidity. It appears, however, that unless there is severe protein-calorie malnutrition the provision of traditional nutritional support has little effect on immune function. Patients receiving TPN are, in fact, probably more likely to suffer infectious complications [9] for the reasons we have outlined above. Enteral feeding may be beneficial when compared with the parenteral route in preserving immune competence, but recently interest has also centred on the use of specific nutrients which may confer unique immunological benefits. These nutrients include glutamine, arginine, RNA, omega-3 fatty acids and trace metals such as zinc.

GLUTAMINE AND IMMUNONUTRITION

The net flux of glutamine from peripheral to splanchnic tissue seen after operative stress and in sepsis in animal and human studies [21, 83] is thought to occur at least in part in response to increased demand from immunological tissue. Glutamine is utilized at a high rate by lymphocytes [2] and macrophages [67], both as an oxidative fuel and to provide intermediates for synthesis of purine and pyramidine nucleotides which are essential for DNA and RNA synthesis [46]. Lymphocyte and macrophage proliferation depend upon glutamine concentration in culture media [2, 71, 87]. Differentiation of both B- and T-cells cultured *in vitro* [16] and the appearance of interleukins 1 and 2 [10] in cell culture have been shown to be glutamine dependent, as have antibody production and macrophage phagocytic capacity [92]. It appears that the rate of utilization of glutamine by these cells depends upon the external concentration of glutamine. It is possible, therefore, that some of the immune dysfunction seen after stress, trauma and sepsis is due to glutamine deficiency. Increased lymphocyte proliferation and increased macrophage activity have been reported after glutamine feeding in septic rats [49, 95], and in humans glutamine-enriched TPN appeared to maintain immune function after bone marrow transplant in that there was a reduction in incidence of infectious episodes and shorter stay in hospital [101]. There are, as yet, no published studies addressing the effect of glutamine-enriched feedings on immune function during critical illness in humans. Gottschlich and colleagues administered glutamine enterally in varying concentrations to patients for 4 weeks after burn injury and failed to demonstrate any positive benefits; however, the total daily intake of glutamine was not stated [30]. As we have already noted, however, it may not be possible to provide sufficient glutamine by the enteral route to increase plasma concentrations and thus to produce specific changes in immune function during critical illness.

ARGININE, OMEGA-3 FATTY ACIDS AND RNA

Animal studies have supported the use of nutritional supplements such as arginine, omega-3 PUFAs and RNA to boost immune responsiveness after surgery or trauma. There is no published work evaluating the effect of nutrition supplemented with any of these substances alone on infectious morbidity or mortality in patients; however, they are marketed together commercially in an enteral feed (Impact, Sandoz Nutrition, Bern, Switzerland) which has been evaluated in postoperative patients. Arginine is an essential amino acid during growth, and may become essential in catabolic states. Supplementary dietary arginine has been shown to have useful effects on cellular immunity in laboratory animal studies, resulting in increased thymic size, enhanced lymphocyte proliferation to mitogen and alloantigen, augmented macrophage and natural killer cell lysis of tumour targets and increased lymphocyte interleukin 2 production and receptor activity [45]. Arginine is the precursor for nitric oxide which is now recognized to be a ubiquitous cellular messenger with important immune functions. Rats fed an arginine-enriched diet survived longer after an intraperitoneal bacterial challenge than control animals [69], and arginine-enriched TPN improved survival in rats after caecal ligation and puncture [56]. In postoperative cancer patients, diet supplemented with arginine resulted in recovery to baseline levels of the proliferative response of lymphocytes to concanavalin A and phytohaemagglutinin by day 4, and increased responses by day 7. Patients fed a glycine-supplemented diet showed no such recovery of response [17]. Of interest, patients receiving arginine supplemented feeding also had increased IGF-1 concentration and improved nitrogen balance. No differences in infection rates or outcome between groups were seen in this study, however.

Prostaglandin E_2 (PGE_2) is thought to be an important factor in the generalized immunosuppression which follows major injury. Leucocyte function is suppressed by PGE_2 in culture [29], and high concentrations of PGE_2 are found in the serum of burns patients [68]. When PGE_2 production is blocked by administration of indomethacin after major surgery there is restoration of the immune response and decreased opportunistic infections [25]. Omega-3 and omega-6 PUFAs are essential dietary constituents as they are the sole precursors of eicosanoid metabolites, which include prostaglandins, lipoxins, thromboxanes and leukotrienes. If the diet is rich in omega-3 PUFAs there is suppression in the production of a number of dienoic eicosanoid metabolites with increased production of trienoic metabolites which have lower biological potency. Of particular importance, PGE_2 is replaced by PGE_3, TXA_2 by TXA_3 and PGI_2 by PGI_3. Enteral feeds rich in omega-3 PUFAs lead to suppression of PGE_2 production, an action which is probably as effective as pharmacological administration of cyclo-oxygenase inhibitors such as indomethacin.

Guineapigs recovering from burn injury fed an enteral diet rich in omega-3 PUFAs showed improved immune and metabolic function [1]. Improved survival was seen in guineapigs after exposure to endotoxin challenge [60] and in rats after intra-abdominal implant of a faecal agar pellet [6] who were fed with omega-3 PUFAs commencing before the insult. In burns patients omega-3 PUFAs improved survival, reduced infectious complications and diminished immunosuppression secondary to blood transfusion [31]. Some other animal studies have failed to show an advantage of omega-3 PUFAs in sepsis, however, especially when treatment is started after the insult [39]. Blocking the production of PGE_2 may not always be desirable as the precise role of PGE_2 in the immune response after major insult has not been fully defined. In the early stages after trauma or sepsis PGE_2 may actually have advantageous immunomodulatory effects, perhaps through suppression of the release of other cytokines such as tumour necrosis factor (TNF). After these first stages of injury or infection there is at least some evidence that a reduction in PGE_2 levels may reduce immunosuppression [72]. There may also be some disadvantages to the use of omega-3 PUFAs. In addition to reducing PGE_2 activity, TXA_2 activity is also reduced. This eicosanoid is of importance in the maintenance of vascular tone and in platelet aggregation. PGI_3 which is produced rather than PGI_2, however, has similar biological potency and is both an important inhibitor of platelet aggregation and a vasodilator.

Theoretically, therefore, a diet high in omega-3 PUFAs may predispose to vasodilatation and prolonged bleeding times. Indeed, Greenland eskimos, whose diet is high in fish oils rich in omega-3 PUFAs do have a prolonged bleeding time [72]. The risk of platelet dysfunction remains a concern despite there being no demonstrable increase in bleeding times in critically ill patients given omega-3 PUFA diets. Those studies addressing the issue however have only included small numbers of patients. A more serious concern associated with the use of omega-3 PUFAs is the recognition that diets high in PUFAs can lead to generation of lipid peroxides and consumption of the natural free-radical scavenger, vitamin E. Free radicals and lipid peroxides produce cellular and tissue damage, which raises the possibility that the administration of omega-3 PUFAs may exacerbate the pathological processes associated with the development of multiple organ failure. It is not known whether these concerns are valid in clinical use, or whether any potential increase in lipid peroxide stress could be prevented by concomitant vitamin E administration.

Dietary RNA may be necessary to maintain normal immune function. Nucleotides increase protein synthesis, and are involved in the regulation of several T-cell-mediated immune responses [11]. In an animal model, administration of RNA significantly improved host immune responsiveness and host survival to a septic challenge whereas a diet free of nucleotides resulted in decreased interleukin 2 production, decreased cell-mediated immunity, decreased allograft rejection and reduced resistance to infection [26]. Heyland, Cook and Guyatt, however, in a review of the evidence from all published studies concluded that there is as yet little evidence to support the use of dietary RNA supplementation to prevent infectious complications in critically ill patients [39]. Impact, the commercially available enteral feed supplemented with RNA, arginine and omega-3 PUFAs together has been evaluated in postoperative surgical patients. Nitrogen balance was greater, lymphocyte responsiveness restored, and infectious and wound complications reduced (11% *vs* 37%) in patients given Impact when compared with a group receiving a standard diet after surgery for upper gastrointestinal malignancy; however, the Impact group received a higher daily nitrogen intake [18]. Mean length of hospital stay was also reduced for patients in the supplemented group (16 *vs* 20 days). In another study involving post-surgical patients receiving Impact *vs* an isonitrogenous control diet, T-lymphocyte counts, B-lymphocyte indices, mean immunoglobulin M and G concentrations and mean interferon-gamma after phytohaemagglutinin stimulation were higher in the supplemented group [44]. Cerra and colleagues randomized critically ill trauma patients to Impact or a standard feed and demonstrated greater immune cell proliferative responses *in vitro* [13]. There were no differences in infections or mortality; however, the sample size was small. In a much larger group of critically ill patients Bower, Lavin and LiCari failed to demonstrate a reduction in the overall number of infections in the Impact-treated group, although the number of urinary tract infections was reduced [7]. Length of stay in the ICU was significantly shorter in those patients receiving Impact. Impact appears, therefore, to have some immunological advantages over standard feeds; however, further controlled trials of its use in critically ill patients are needed.

OTHER 'IMMUNONUTRIENTS'

Zinc has an important role in the maintenance of immune function, in promotion of wound healing and in maintenance of intestinal mucosal integrity. Zinc deficiency is associated with reduced concentrations of IGF-1 and reduced rates of protein synthesis [40]. In certain conditions, zinc deficiency is particularly likely. These include severe burns, pancreatitis and patients with excessive loss of gastrointestinal fluid. Urinary excretion of zinc increases with the degree of catabolic stress. Supplemental zinc therapy is recommended during critical illness, guided by regular monitoring of serum zinc concentrations [97].

Some workers have recommended the use of branched chain amino acids or increased doses of antioxidants such as vitamins E and C. There is no work available at present supporting these interventions in critically ill patients [39].

Conclusion

The potential importance of nutritional manipulation in the prevention and management of multiple organ failure occurring as a complication of critical illness is increasingly recognized. Despite much evidence from studies in animal models of sepsis, shock and organ failure, there is as yet little direct evidence in patients with critical illness to support the therapies currently advocated by some workers. Indirect evidence of efficacy is present for some nutritional manipulations from studies in elective surgical patients. The relevance of studies in animal models and in elective patients to patients with critical illness is unclear, however, and large randomized controlled trials are needed before definite pronouncements can be made.

From the evidence that is available can any conclusions be drawn? The enteral rather than parenteral route should be chosen for nutritional delivery in critical illness when possible. The use of enteral nutrition appears to be associated with a reduced incidence of sepsis and likelihood of developing multiple organ failure. At present, there is fairly convincing evidence that glutamine deficiency is a significant problem in critical illness. Addition of glutamine to parenteral nutrition solutions may ameliorate or even prevent the deleterious effects of glutamine deficiency on the gut, the immune system and on muscles. Addition of glutamine to TPN may offset some of the disadvantages demonstrated to be associated with the use of TPN. The efficacy of glutamine-enriched enteral feeding is less clear, however, and unfortunately only enteral glutamine-enriched feeds are widely available commercially. The enteral feed Impact, which contains arginine, omega-3 PUFAs and RNA appears to have useful effects on immunocompetence in elective surgical patients, and it is tempting to extrapolate these to the critically ill. The potential adverse effects of increased lipid peroxide generation in patients with multiple organ failure given omega-3 PUFAs is of concern, however, and the results of formal trials should be awaited before PUFA-enriched feeds are used routinely in the ICU.

There is much exciting work to be done in the field of nutrition and immunonutrition in critical illness, and it is likely that future improvements in intensive care outcomes will depend at least in part upon choice of nutrients and their route of supply.

CORRESPONDENCE

Pre-emptive analgesia with NSAID—what does it achieve?

Sir,—We wish to comment on the study of Espinet and colleagues [1] who investigated the combined effect of thoracic extradural local anaesthetic block and administration of diclofenac either 30 min before or 30 min after skin incision on post-hysterectomy pain and analgesic consumption. They found that the timing of analgesia made no difference to pain scores or postoperative analgesic requirements, that is there was no pre-emptive effect of diclofenac and extradural local anaesthesia. They discussed these findings in relation to the known actions of non-steroidal anti-inflammatory drugs (NSAID) in inhibiting peripheral sensitization of the primary afferent nerve terminal and so reducing afferent barrage from the periphery. This afferent barrage contributes to central sensitization in the spinal cord and the degree of central sensitization is said to relate to subsequent pain experience and analgesia [2]. The authors comment that the *lack* of pre-emptive analgesia in their study is at variance with that seen in animal studies using similar paradigms.

While their study was designed carefully to exclude the confounding effects of systemic opioids, nitrous oxide and local anaesthetic test doses, the lack of pre-emptive analgesic effect reported in this study may be explained by central actions of NSAID. In addition, not all types of injury are sensitive to pre-emptive treatment, and under certain circumstances central local anaesthetic block may not prevent the subsequent development of hyperalgesia. These possibilities are discussed below.

It is now well established that prostaglandins contribute not only to peripheral but also to central sensitization, and that NSAID act at central and peripheral sites [3]. In experimental models of central sensitization, intrathecal administration of NSAID results in antinociception [4, 5], and critically, their central action is equally effective whether administered *before or after* the noxious stimulus. This is because they act on intracellular messengers responsible for the maintenance of the persistent nociceptive state in the spinal cord [6]. In humans, systemically administered diclofenac crosses the blood–brain barrier and CSF concentrations may continue to increase for 12 h after a single dose [7]. Therefore, in the study of Espinet and colleagues [1], a central spinal action of diclofenac, reducing central sensitization with equal efficacy either before or after incision, could potentially have obscured any pre-emptive action of extradural bupivacaine. A recent study using pre-emptive *vs* post-injury ketorolac *did* show a small initial opioid sparing effect. However, ketorolac may cross the blood–brain barrier to only a minimal extent and so inhibition of peripheral afferent discharge may not have been obscured by the central actions of the NSAID in this study [8].

Animal studies also show that pre-emptive analgesia may not be effective in all types of injury; Dougherty, Garrison and Carlton [9] have reported that pre-emptive topical administration of lignocaine to the sciatic nerve could ameliorate the development of hyperalgesia in a loose ligation model of nerve injury (a model that shows a marked response to a number of pre-emptive analgesic techniques) [10]. However, Dougherty, Garrison and Carlton [9] also reported that lignocaine showed no pre-emptive effect in a partial transection injury of the sciatic nerve. If different types of injury are differentially sensitive to pre-emptive local anaesthesia, the implications are that some aspects of surgical trauma may not be sensitive to pre-emptive local anaesthetic block. Therefore, differences in operation type and operative technique may contribute to the different outcomes in clinical studies of pre-emptive local anaesthesia.

Furthermore, the *route* of pre-emptive local anaesthetic administration may influence the development of post-injury hyperalgesia. For example, Tverskoy and colleagues [11] reported that spinal anaesthesia with bupivacaine was less effective than local infiltration of bupivacaine in reducing late postoperative wound pain after hernia repair. This is a surprising finding in the light of the common perception among anaesthesists that spinal anaesthesia is more reliable and complete than local infiltration. One initial suggestion given to explain these findings was that topical local anaesthesia may have had an anti-inflammatory effect at the site of the wound [12]. Alternatively, Luo and Wiesenfeld-Hallin have recently reported [13] that while *intrathecal* local anaesthetic initially produces profound block of sensory transmission, as the local anaesthetic wears off, a paradoxical state of spinal hyperexcitability ensues. This may completely mask any previous benefit. More importantly, no subsequent *long-term* behavioural benefit could be shown from pre-emptive *intrathecal* lignocaine, even compared with animals which received no intrathecal lignocaine (although in contrast, topical local anaesthetic to the sciatic nerve has previously been shown to be beneficial with this same nerve injury model [14]). The authors also pointed out that the marked clinical benefit shown by Bach, Noreng and Tjellen in their well known study [15] in amputees was achieved using a combination of extradural local anaesthetic *and* opioid.

Pre-emptive analgesia as a concept has essentially been assumed to relate to inhibition of the afferent barrage, especially the initial "injury discharge" associated with the primary event such as nerve injury. As has been emphasized previously [16], the injury discharge may outlast the treatment and so obscure the benefit implied by some animal studies. Furthermore the following factors: (i) giving drugs that act not only on injury discharge but also on the substrate of the central sensitized state, such as NSAID; (ii) the differential sensitivity of different types of nerve injury to pre-emptive analgesia; and (iii) the recent experimental evidence that intrathecal local anaesthetic *alone* may have little benefit in terms of reducing subsequent central sensitization; all help to explain some of the disappointing findings in clinical studies of pre-emptive analgesia but conversely these same observations will help in the design of better regimens to prevent pain.

Sir,—Thank you for the opportunity to reply to Hudspith and Munglani. On the whole we concur with their comments. The complexity of pain production and the number of mechanisms involved make it difficult to block or reduce the nociceptive input. This almost certainly accounts for the lack of a useful pre-emptive analgesic effect in the clinical setting. It is unlikely that one single analgesic method will be sufficient and we should look towards a multi-modal approach to pain relief/reduction. In a small part this is what we tried to achieve in our study. Further research into this field is needed.

Cytokine balance and immunosuppressive changes at cardiac surgery

Sir—The study of McBride and colleagues contains much useful information on the immunological changes associated with surgery [1], but omitted several important aspects. We would welcome the authors' comments on the following points.

The authors mention briefly that beta adrenoceptor blocking drugs may alter the pro-inflammatory cytokine response, but the possible effect of other cardiac drugs is not considered. Could calcium channel antagonists also have changed the cytokine response? It has been shown in an animal model that administration of calcium antagonists, either before or after endotoxin administration, exerted a protective effect and decreased mortality [2, 3]. Some cytokines exert their effects by increasing free intracellular calcium, especially IL-4, which is one of the principal cytokines in TH2 lymphocyte development [4]. A decrease in intracellular calcium concentration after calcium channel block may decrease amplification of the initial cytokine signal by interfering with the IP$_3$–calcium–calmodulin pathway. In contrast, it has recently been shown that diltiazem enhanced production of cytokines and maintained immune function after haemorrhage [5]. It seems that cations, and Ca^{2+} in particular, may have important intracellular influences on immune function, and therefore any comparisons between McBride's *in vivo* and *in vitro* cytokine changes must be interpreted with great caution.

In describing the activation of TH2 cells and the increase in IL-10 as key events in an anti-inflammatory response to cardiac surgery, the authors failed to mention that the principal immunological fault after major surgery and trauma is impaired production of TH1 cytokines (interferon gamma, IL-2). These cytokines are crucial for the development of TH1 lymphocytes, which are largely responsible for cell-mediated immunity [6, 7]. Development of TH2 lymphocytes is dependent on the early production of IL-4 (TH2 cytokine) *in conjunction with* down-regulation of interferon gamma and IL-2 [6, 8]. Whether TH2 lymphocyte activity is favoured when TH1 lymphocyte production is suppressed is unclear, but no increase in IL-2 or IL-4 was found during or after cardiopulmonary bypass [9].

The statement that oxpentifylline induces TH2 activity is misleading [10]. This phosphodiesterase inhibitor increases intracellular cAMP concentration which stimulates PGE$_2$ synthesis, resulting in impaired IL-2 synthesis and abnormal TH1 development. Because IL-4 synthesis is not affected, TH2 activity is unaffected. Therefore, preferential TH2 development occurs as a result of inhibition of TH1 lymphocytes [10]. Indeed, failure of IL-2 production is considered to be a major factor in the impaired cell-mediated responses after surgery and trauma [11, 12].

It is clear that there are many factors involved in the immunosuppression after cardiac surgery and the changes in IL-10, IL-1ra and sTNF alpha observed by the authors only play a part.

Sir,—Sheeran and Hall sought to highlight the potential immunomodulatory effects of calcium antagonists at cardiac surgery. Their comments suggest that calcium antagonists may have influenced the cytokine response.

We have since investigated the balance of pro- and anti-inflammatory cytokines in plasma and bronchoalveolar lavage of children undergoing surgery for congenital heart disease. None of these children received preoperative calcium antagonists. Nevertheless, their cytokine response was similar to that observed in adults, with a phased anti-inflammatory response developing, beginning with IL-10, 10 min after aortic cross-clamp release and followed by IL-1ra and the TNF soluble receptors over the next 24 h. In the absence of calcium antagonists these children were able to mount a phased anti-inflammatory response [1]. The existence of a phased anti-inflammatory cytokine response cannot therefore be attributed to the presence of calcium antagonists.

It is not yet known what factors if any influence the magnitude of the phased anti-inflammatory cytokine response and what clinical significance variations in magnitude of this phased anti-inflammatory cytokine response may have. Our group is actively investigating this, and it is indeed possible that calcium antagonists (including volatile anaesthetic agents) may influence the magnitude of this response.

The cytokine response in patients and the isolated CPB system differed in that there was no increase in anti-inflammatory cytokines *in vitro*. [2]. Because of the known effects of Ca^{2+} on immune function, Sheeran and Hall advise "great caution" in comparison of the cytokine response within patients and the isolated CPB circuits. Cautious comparison of the two systems indicates that the major difference between patients and the isolated CPB circuits is not the absence of calcium antagonists but rather the fact that within the isolated CPB circuit blood does not have an opportunity to escape from the activating non-endothelialized surface of the CPB apparatus and enter the vasculature of the patient. We believe that this is vital to any interpretation of these differences.

Sheeran and Hall described impaired production of TH1 cytokines as "the principal immunological fault" at major surgery and claimed that we failed to mention in our discussion such an "immunological fault". There is nothing new in describing the immune response at cardiac surgery as "being at fault". For years authors have concentrated on the pro-inflammatory response and immunosuppression at cardiac surgery as two aspects of disordered immunological homeostasis. Sheeran and Hall have simply gone further than most in speculating on the "principal" of these so called "immunological faults".

We recommend a fresh approach to investigating immunological change at cardiac surgery. We believe that an alternative and helpful way to investigate the immune changes at elective cardiac surgery is to view the immune changes therein as a model of a successful and indeed appropriate response. Most patients for elective coronary artery bypass grafting (CABG) surgery now go home 5 or 6 days later. Surely this is an example of outstanding immunological success! Let clinical outcome be the arbiter as to which aspects of the immune response at cardiac surgery are at fault.

The cardiac surgical patient with good clinical outcome presents an excellent model for study of a successful immune response. We have been the first to highlight the phased anti-inflammatory response as a possible contributor to this success. Other workers have later described an IL-10 response after cardiac surgery [3]. We have never suggested that the phased anti-inflammatory response which we have described is limited to IL-10, IL-1ra and TNF soluble receptors. In fact it is likely that IL-4, TGF-β and indeed other as yet undiscovered anti-inflammatory cytokines may play an important role in the success of our patients.

Only when the ingredients of a successful immune response such as occurs at cardiac surgery are understood shall we understand when the immune response is "at fault". We believe that it is important to know when the immune response is at fault. This information will only come through comparing the profiles of the immune response of cardiac patients who do well with those who (rarely) go on to develop the systemic inflammatory response syndrome (SIRS) or indeed infective complications such as mediastinitis. This knowledge may then enable us to devise effective strategies in the prevention and early treatment of SIRS in the context of major trauma and non-cardiac surgery. We may even be able to predict those patients at risk of developing severe infective complications.

Sheeran and Hall pointed out that our statement that oxpentifylline induces TH2 activity is misleading. We thank them for this and highlighting that the preferential TH2 development after oxpentifylline treatment is an indirect result of inhibition of TH1 development by the drug.

Immunomodulation in the treatment of SIRS in the ICU has been largely unsuccessful. An air of despondency has descended upon the literature [4]. This may be because we have been too quick to modulate the immune response without fully understanding what is an appropriate response to trauma and sepsis. Perhaps it is time to re-evaluate the cardiac surgical patient as a model of success and then re-design our immunomodulatory strategies accordingly.

Perioperative changes in α_1-acid glycoprotein concentrations

Sir,—Booker, Taylor and Saba [1] suggested that preoperative measurement of α_1-acid glycoprotein (AAG) concentration should be performed in all infants undergoing major elective surgery who are expected to receive prolonged bupivacaine infusions in the postoperative period. This is based on concern that bupivacaine toxicity may be related to low plasma concentrations of the drug binding protein. Unfortunately, this concern is, in turn, based on several dubious premises: (1) that plasma protein binding of drugs may have significant pharmacodynamic implications; (2) that changes in protein binding are important clinically for drugs which are highly bound, such as bupivacaine; and (3) that if variations occur in plasma concentrations of AAG, then free plasma concentrations of the drug can vary considerably, whereas the total concentration of the drug in plasma is only slightly affected. To explain these misconceptions is a long story—I refer the authors to a few recent publications [2, 3]. Premise (3) is the incorrect way round; if the *fraction* of bupivacaine bound in plasma changes as a result of a change in AAG concentration, classical pharmacokinetic theory predicts that, in the case of a low hepatic extraction drug such as bupivacaine, *total* plasma drug concentration varies but the *unbound* drug concentration does not. As it is the latter which determines pharmacological effect at steady state, there would be no clinical consequence of a change in AAG concentration. Therefore, on this basis, measurement of this protein would be a waste of time and resources. One *caveat* applies to this conclusion, if AAG concentration decreases in proportion to the degree of hepatic dysfunction, then its measurement may be an indirect predictor of the ability of the liver to clear free bupivacaine by metabolism. However, such an association would be independent of the degree of plasma drug binding.

CBF in adults using near infrared spectroscopy (NIRS): potential for bedside measurement?

Sir,—We read with interest the article by Owen-Reece and colleagues [1] and suggest that the findings on correct scaling of NIRS cerebral tissue measurements warrant further discussion.

Comparison between scalp and dural recordings in patients allowed conclusions to be made regarding the percentage of the illuminated tissue volume which was cerebral. Measurement of cerebral blood flow (CBF) with the optodes on the dura compared well with values obtained by invasive techniques, but CBF was underestimated by a factor of 3 with the optodes positioned on the scalp. This can be explained by the cerebral tissues contributing only 30–40 % to the total pathlength. Scalp and skull have been shown to have low blood flow and act as static "deadspace" [2]. The chromophore concentration changes detected by NIRS are mostly cerebral, but they must be seen and expressed as concentration changes occurring in the total illuminated tissue volume, 60–70 % of which is extracerebral in the adult. In a rat model [3] and in neonates [4] it has been postulated that the extracerebral component is less than 20 % of the total optical pathlength and this has been accepted as a minor limitation in these measurements. Previous studies by Elwell and co-workers in adults have alluded to the problem of the relatively small component that the cerebral tissue contributes to the total optical pathlength, but none the less they achieved results for cerebral blood flow comparable with invasive techniques despite using scalp recording [2]. The small cerebral component of the total interrogated volume has major implications for the clinical use of such a system as a small alteration in the cerebral tissue volume has a large effect on the proportions of cerebral and extracerebral tissue in the total illuminated tissue volume and thereby has a major effect on measurements of changes in chromophore concentration. The proportion of cerebral tissue may vary between subjects or even within a subject because of changes in optode/scalp coupling or pathological changes, for example in cerebral oedema when the proportion of brain in the illuminated tissue volume may increase as the brain is forced against the skull. In these circumstances, is the instrument measuring quantified changes in chromophore concentrations occurring in the brain?

It is not specified that figure 1 is a dural recording, but using the values shown to make an estimate of cerebral blood volume this is likely to be the case. If this is a dural recording, the same re-saturation event performed with the optodes placed on the scalp would cause a corresponding change in [HbO$_2$] over the initial 4 s of only 0.6 μmol litre^{-1}. This value would be of a similar magnitude to the baseline variability of the trace.

Desaturation to 95 % is unlikely to prove harmful and has been used in neonatal intensive care practice. However, many patients in whom measurement of CBF would be particularly useful are likely to be at risk from secondary brain injury, for example head-injured patients. We have reservations concerning the clinical acceptance of a desaturation method in this population.

The potential of NIRS to measure cerebral blood flow remains an exciting possibility, but we would question whether a desaturation/resaturation technique in combination with a scalp recording will ever be satisfactory for this purpose in adults.

Sir,—It is true that we have quoted higher values for cerebral blood flow (CBF) elsewhere [1]. These were obtained with a different flow analysis method which is described more fully in that article. Briefly, accumulation of tracer in the brain is biphasic, with a fast and slow component. Thus in that study, CBF was 59 ml 100 g^{-1} min^{-1} in the first 1.5 s with a second peak of 11 ml 100 g^{-1} min^{-1} at 1.5–3 s. These values are similar to those measured by PET.

We decided not to use this type of analysis for our study [2] for two reasons. First, high and low CBF components are not widely used clinically (and are not, in any case, provided by xenon washout and the Kety–Schmidt method). Second, such treatment may confuse a simple "before and after" comparison. We therefore used a single average value calculated over the first 4 s of tracer arrival which is compared more easily with mean CBF measured by other techniques.

We believe that NIRS is able to quantify changes in brain chromophore concentration but these changes must be observed through the "deadspace" of the non-cerebral tissues. It is true that at present we have difficulty in making allowances for this when subsequently handling the data. However, recent computer modelling shows that the cerebral sulci have little effect on the proportion of cerebral tissue illuminated and also that when the optodes are pressed firmly against the scalp, skin blood flow has negligible influence [Delpy D. T., personal communication]. As stated in our article, it is necessary to determine the contribution of extracerebral tissue to the total optical pathlength before further progress is made. Similar modelling work, which we hope will assist in quantifying the effects of extracerebral tissue on near infrared spectroscopic measurements, is also in progress at UCL Department of Medical Physics and Bioengineering.

The authors are correct in interpreting figure 1 as a dural recording and we apologize that this was not made clear. As they imply, the signal-to-noise ratio is a significant problem in measurements made via the scalp and more scalp measurements were rejected than those from dura.

Desaturation–resaturation is unlikely to be harmful for the reasons outlined in the article. However, we agree that it may be preferable to avoid the technique in brain-injured patients. There is a range of cerebral haemodynamic variables which can be observed using NIRS which do not affect arterial oxygen saturation, for example cerebral blood flow measurement using indocyanine green as a tracer, spontaneous cerebral blood volume changes, cerebral vascular response to altered Pa_{CO_2} and mean cerebral saturation.

In view of the progress being made in dealing with the scaling problems of scalp recording and the scope for other cerebral measurements which can be made non-invasively with NIRS, we agree with Hopton, Walsh and Lee that the potential of the technique is exciting. There is a great deal of work still to be done before it is suitable for widespread clinical use.

Hypercoagulability induced by crystalloids

Sir,—The *in vitro* study by Ruttmann, James and Viljoen [1] in which dilution of blood with saline and Haemaccel was shown to render it hypercoagulable, is fascinating reading. Their results not only challenge intuitive assumptions but also have possible implications for our clinical practice and, perhaps more importantly, call into question the methodology of studies designed to assess the effect of regional anaesthesia on the development of postoperative thromboembolic disease (TED).

The authors cite the *in vivo* study of Janvrin, Davies and Greenhalgh [2] in which patients given crystalloid in the perioperative period ("wet" group) had a higher incidence of deep vein thrombosis (DVT) than those who received none ("dry" group). While this is of course no criticism of Ruttmann, James and Viljoen, it is worth pointing out that this frequently cited study involved only 60 patients and its power was in the region of 0.65 [3].

However, the results of the *in vitro* work of Ruttmann, James and Viljoen are compelling, and notwithstanding the above criticism, if the *in vivo* effect is real then this may present a case for the use of the hydroxyethyl starches (HES) where there is a risk of TED, and where plasma volume expansion is required. This colloid, rather than promoting coagulation, prevents it by inducing a mild and transient type-I von Willebrand-like syndrome [4].

Over the years, several studies have demonstrated to varying degrees the effect of extradural and spinal anaesthesia on the reduction in postoperative thromboembolic disease compared with general anaesthesia. The proposed mechanisms whereby this is effected include reduced blood loss and transfusion requirements, reduced stress response and its concomitant procoagulant effect, improved lower extremity blood flow, and reduction in plasminogen activator inhibitor-1 (PAI-1) in those receiving regional anaesthesia [5–7]. In none of these studies was administration of crystalloid and colloid considered to exert any specific effect on coagulation. Only administration of blood was standardized between the groups. In most reports, the design of the study ensured that haemodynamic variables were controlled tightly and this usually implied that those receiving extradural or spinal anaesthesia were preloaded with up to 15 ml kg^{-1} of lactated Ringer's solution and required ongoing plasma volume expansion with this and similar solutions throughout the case and into the postoperative period to achieve "target" haemodynamic values (although the actual volumes were not recorded).

Again, if the procoagulant effect of crystalloid haemodilution is real then it may to some extent mask the beneficial effects of regional anaesthesia if crystalloid is used to preload these patients, and this may provide support for the argument that normotension should be maintained either with vasopressors or HES. Clearly, this work needs to be re-evaluated in the light of any new understanding of the effect of crystalloid haemodilution.

Sir,—We agree fully with the comments that our results challenge intuitive assumptions and we agree entirely with the inferences they draw from these results. Furthermore, as Farmery and Kong correctly point out, our results may indeed call into question not only the methodology of studies designed to assess the effect of regional anaesthesia on the development of postoperative thromboembolic disease, but also the methodology of most of the currently quoted studies designed to assess the effect of any of the colloids on coagulation, as the majority use a crystalloid control group.

Whether or not our *in vitro* results can be translated to the clinical situation remains to be resolved. However, we are currently in the process of investigating this effect in human volunteers and the results appear to be consistent with our *in vitro* work. Indeed, using standard tests of coagulation and also thrombelastography, we have been able to further strengthen our hypothesis that haemodilution renders blood hypercoaguable.

We can only agree with the comments of Farmery and Kong that the role of crystalloid solutions needs to be re-evaluated, especially in those circumstances in which the prevention of procoagulant states is desirable.

BOOK REVIEWS

Fibreoptic Guided Tracheal Intubation—A Practical Approach. N. C. HWANG. Published by McGraw-Hill, Singapore. Pp. 81; illustrated. Price $9.15.

This is a splendid little book which was a pleasure to read. At first sight it appears slim and one wonders how it can cover fibreoptic guided tracheal intubation sufficiently. It appears to be the author's aim to give a "practical approach" and not excess theory. The book is precise, readable and ideal for the trainee who is interested in learning the basics of this technique before gaining any practical experience. For an accomplished operator of the fibreoptic scope, this book is deficient in detail but it does offer some useful guidelines on how to set up a fibreoptic training programme. It also contains good diagrams and photographs but unfortunately they all appear at the end of the book which makes referring to them while reading the text rather tedious. The author has described useful aids for fibreoptic intubations. However, I feel that either diagrams or pictures of the various aids would have been more useful for those who may neither have seen nor used them previously. The chapter on cleaning and maintenance of the fibreoptic scope was well done. However, despite my enthusiasm, the book does have some weak points. The lack of detail in some areas may be misleading to the novice user of the fibreoptic scope, for example administration of local anaesthetic via a cricothyroid puncture is given as a method of anaesthetizing the trachea but there is no mention of complications or suggestions of alternative methods such as using a cannula instead of a needle. The skill acquisition section suggests teaching fibreoptic intubation with patients who are breathing spontaneously (p. 46), again without discussing the drawbacks of this method or alternative methods.

In conclusion, this book is useful for the trainee who wishes to gain a basic knowledge of the fibreoptic scope and fibreoptic intubation at a reasonable price. However, it lacks detail in some key areas.

M. C. Mushambi

Clinical Scenarios in Anaesthesia. W. A. CHAMBERS AND R. E. PATY. Published by Churchill Livingstone, Edinburgh. Pp. 181; indexed. Price £29.50.

The introduction of the simulated clinical into the first part of the "new" FFARCS examination was rightly seen as a major innovation in objectively testing the diagnostic and therapeutic knowledge of candidates. This book has been published to coincide with the change to a two part examination for the diploma of FRCA in which the structured clinical moves to the final part. The book consists of 47 case reports accompanied by follow-on questions, with space for answers, interspersed with further information. A list of recommendations for further reading completes each section. The subjects of the reports are diverse, ranging from the routine (haematemesis, hypercapnia and brachial plexus block) to the esoteric (myotonic dystrophy in pregnancy, aeromedical transport and thymectomy); no claim is made that the whole gamut of the guidelines for the final examination is covered.

Unlike books written specifically as guides to the structured clinical, the format of this book does not follow exactly that of the present examination. The rubric to the majority of examination questions consists of a very short paragraph of history, usually only five or six lines, followed by the results of a physical examination and relevant investigations. The case reports in the book vary from one half to 2.5 pages in length, frequently taking the reader to the end of an operation. In some cases radiographs are pictured, in others clinical photographs and blood chemistry results; there are no electrocardiograph records. This format, while interesting, does not attempt to mimic that of the examination. The vast majority of the current trainees eligible to take the final examination will have seen this format in part I of the present examination; a cohort to whom this format is unfamiliar will soon, however, present themselves.

The questions which follow the scenarios, while covering important topics, frequently do not lead the reader or candidate down a seamless path of thought. Thus a scenario on the conduct of anaesthesia for renal transplantation is followed immediately by a question on the criteria for brainstem death and a report of carotid artery surgery by several questions concerning diabetes. The authors state that the book "sets out to ask more questions than it answers" and "The conduct of the cases is not always the only or necessarily the best technique and the reader is invited to consider whether he or she would have acted differently...". It is doubtful if candidates with less than 3 yr in the specialty are in a position to consider the merits of the treatments as outlined. They might perceive than an induction sequence consisting of thiopentone, gallamine and suxamethonium which leads to anaphylaxis is, to say the least, unusual but they may not be aware that total i.v. anaesthesia with propofol in a 12-yr-old boy undergoing brain biopsy is not a universally accepted technique. To be at their most useful each report might be considered by a tutorial group led by a consultant whose specialty is being addressed. There are inherent dangers in printing sub-optimal treatments in a book targeted directly at inexperienced trainees who may subsequently recall a technique without remembering whence it came and that it was inappropriate.

Moving the structured clinical to the final examination has undoubtedly created a need for books which cover the increased clinical scope of this part of the examination. This book claims to meet this requirement but its format is, in most instances, different from that of the examination. Many of the scenarios are long and detailed, and contain pitfalls for the unwary. Unless potential candidates are guided through the reports, information may be retained which will not stand them in good stead in either the examination or clinical practice. Arguably, readers find that case reports form the most interesting part of medical journals and the scenarios in this book undoubtedly form a very good basis for discussion. It might be suggested that in a second edition the authors might like to consider changing the format of the book either to make it more closely resemble that of the examination or specifically to form the basis for a series of consultant-led tutorials.

D. Saunders

The Cambridge Dictionary of Statistics in the Medical Sciences. B. S. EVERITT. Published by Cambridge University Press, Cambridge. Pp. 277; illustrated. Price £12.95.

All medical researchers require a working knowledge of statistics, but the large number of statistical techniques available, together with recent developments in statistical and computational methods, implies that most individuals will encounter unfamiliar statistical terms in their work. This dictionary addresses this need. Although it was aimed primarily at medical statisticians and students, the author expresses a hope that it will be useful both to medical researchers and clinicians. It comprises 277 pages, and typically there are eight entries per page. There are 70 figures which are used mainly to illustrate graphical techniques, such as the box-and-whisker plot, although probability density functions are also presented graphically.

The type of entry covers a wide range. Medical audit is a defined entry; at another extreme, projection pursuit is included. The coverage tends to be superficial; this is not a textbook and cannot be used as a recipe book to guide the researcher through data analysis. However, the coverage is thorough. In a 6-month period from July to December 1995 all but four statistical tests used in the articles in the *British Journal of Anaesthesia* are included.

The dictionary is extensively cross-referenced, although there is a tendency in some entries for these to be circular. Thus in the excellent entry on "likelihood" there are cross-references to seven other entries, three of which simply lead back to the original. On the whole, abbreviations are dealt with well. For example "least significant difference" appears in the dictionary as a full entry, and this is also referenced as "LSD".

Several of the entries lend themselves to a mathematical treatment and equations are presented. More than 50% of the pages contain some mathematical expressions. The typesetting of equations is clear, with appropriate fonts for operators, brackets and subscripts. The presentation of more mathematical entries assumes a working knowledge of mathematics, including matrix algebra.

The dictionary does not include references to definitive sources. For most entries this is unnecessary, but in some cases it would be helpful. For example, the entry on cluster analysis leads to several related items; a reference to a source which gives a more exhaustive account would help to complete the picture.

Two types of user will benefit from this book. First, the researcher or clinician requiring a summary of a statistical technique that appears in a journal article, and second, the clinician with some knowledge of statistics and a short attention span. There is something of interest on every page; this reviewer enjoyed it very much.

C. J. R. Parker

The Massachusetts General Hospital Hand Book of Pain Management. D. Borsook, A. A. LeBel and B. McPeek (editors). Published by Little, Brown & Co., Boston. Pp. 458; indexed; illustrated. Price £24.00.

There are several large volumes on the management of pain but a niche exists for a small pocket handbook such as this. It is aimed at all health workers who treat patients with chronic pain. It provides an introduction to the management complexities, assessment tools and multiple treatment modalities that are now available.

The book is divided into four sections; the first deals with general issues in pain management and includes good chapters on the neural basis of pain and assessment of pain. The second section deals broadly with diagnostic procedures and therapeutic options and the third section is on the treatment of specific pain syndromes. I was pleased to see that the procedures described were generally undertaken in theatres with monitoring, image intensification and safe recovery facilities. This standard of practice is unfortunately not always achieved everywhere in the UK. The last section is entitled "Special considerations" which, while interesting, could have been incorporated into earlier sections, hence avoiding some repetition.

The handbook is not referenced; however, the suggested reading at the end of each chapter is generally modern and relevant. Two of the seven appendices include useful information such as diagrams of dermatomes and nerve distribution, and the IASP (International Association for the Study of Pain) classification of chronic pain, but the remaining appendices, while interesting, are only of specific relevance to doctors practising in North America.

There are some limitations. It is a multi-author book and as such the quality of chapters is variable. There is inevitably repetition but for newcomers to pain management this can be helpful. The x-rays have not reproduced well but the line diagrams are clear. However, the book reflects North American practice, for example in its emphasis on psychological management (which is not necessarily bad as I believe we tend to be somewhat repressed on this side of the Atlantic!). Recommended drug treatments reflect international differences both in generic and brand names, for example meperidine/pethidine, acetaminophen/paracetamol.

Overall this book presents a rational approach to the multidisciplinary management of pain which is both easy to read and conveniently lightweight. It fills a definite gap in the market and represents good value for those involved in the management of patients with chronic pain and for trainees studying for examinations.

F. A. Campbell

Clinical Anaesthesiology—International Practice and Research—Obstetric Anaesthesia. D. G. Bogod (editor). Published by Baillière Tindall, London. Pp. 174; indexed. Price £30.00.

Many books on anaesthesia become outdated in some aspects at the time of publication. I am pleased to say that this is not the case with this book. There are 10 concise topics, each examining relevant aspects of modern obstetric anaesthetic management, and each by a different author.

Many problems in medicine are caused by ignorance of the aims and problem of other specialties, particularly when those specialties work closely together. To try to improve the anaesthetist's knowledge of obstetrics, the first section is a resumé of modern labour management written by an obstetrician. This section makes particular reference to preterm, breech and multiple deliveries, all of which may involve anaesthetic intervention. Many mothers are now aware of the benefits of extradural analgesia but often question the obstetric anaesthetist or midwife about potential complications. Problems of backache, headache and neurological complications are ably dealt with in a section on the long-term effects of extradurals.

There are sections on new drugs and techniques used in obstetric anaesthetic practice, particularly the use of epispinal techniques and the increased use of spinal and extradural opioids. To complement this there is a section on the neonatal effects of opioids in labour. It states reassuringly that most regimens in common use appear to be safe.

Two other sections complement each other; one a very forthright appraisal of regional techniques for Caesarean section, spinal, extradural and combined techniques, emphasizing the very rare need for general anaesthesia for Caesarean section, the other a section on general anaesthesia for Caesarean section. This is a very thoroughly researched section but in many ways the most disappointing. It is very long-winded and contains at the end a failed intubation drill so long that, if it needed to be referred to in an emergency, I fear the mother's demise long before the end of the algorithm.

Another rather long section deals with audit. Sadly this deviates somewhat from specific obstetric anaesthetic audit and describes anaesthetic audit in general.

There is an excellent section on high-risk pregnancy, with a major emphasis on obesity and asthma, and the management of cardiovascularly and neurologically compromised mothers. The section on feeding in labour gives a clear account of the benefits and potential dangers of feeding mothers in labour. Medico-legal considerations of obstetric anaesthesia are admirably dealt with in the final section in the book.

In short, this is an excellent book and should be of use both to practising obstetric anaesthetists and trainees alike.

R. J. S. Birks

Low Flow Anaesthesia. J. A. Baum and G. Nunn. Published by Butterworth–Heinemann, Oxford. Pp. 208; indexed; illustrated. Price £35.00.

With increasing interest in low flow anaesthesia and the advent of new agents, this books provides a major and timely contribution to the literature. It is a well written and easily read comprehensive review of a potentially difficult subject.

The book successfully covers most aspects of the use of low flow systems. One criticism is that the classification used by the author, while well explained, is confusing. It uses the old terms of semi-open and semi-closed, and may also cause confusion by describing systems such as the Magill and Bain as non-rebreathing systems. The rationale behind the classification given is presented clearly but I am sure it will be a source of annoyance to those accustomed to other classifications. That criticism aside, the book is full of useful information. In particular, several chapters are outstanding. The uptake of anaesthetic agents is well written and easy to follow. Mathematics are present in this book, but are used appropriately, are well diluted by "common sense" text and can be ignored by non-mathematicians without losing the meaning of entire chapters. There is an excellent discussion of the various models of anaesthetic uptake. The chapter on anaesthetic methods for low flow anaesthesia will be useful to all trainees. Of general interest is the exhaustive discussion of the cost implications of low flow anaesthesia.

There is an extremely useful chapter on the newer anaesthetic machines, how they function in relation to flow and the technical requirements of using low flows. The section on monitoring requirements and safety aspects is comprehensive, with lists of the standards and guidelines that are required both at the present time and in the near future. There is a short but informative chapter on substances which accumulate in low flow systems. It is regrettable that at the time this book was written, the newer inhalation agents were only just beginning to become available and there is limited but nevertheless useful discussion of these agents. There is also a very brief section on the use of low flow anaesthesia in paediatric practice.

The information in this book should be available in any department that is intending to use either low or minimal flow anaesthesia. It is a topic that few major texts cover adequately and in which it is almost impossible to find a book that is comprehensive, informative and yet readable. This book achieves these objectives. It is an excellent reference book suitable not only for departments but also for individuals.

N. Soni

Total Burn Care. D. N. HERNDON (editor). Published by Saunders, London. Pp. 597; illustrated; indexed.

This book comprises 597 pages covering 60 chapters. It is written by 82 international authors, mainly from the USA, with a few from the UK, Austria, Australia and Japan, many of whom are well known experts in this field. The book is set out in nine sections.

The first section is a brief introduction of the burn management team and the epidemiology of burns in the USA. It emphasizes the multidisciplinary approach to the care of burns. The second section covers immediate care of burns and includes burn disaster management, pre-hospital care and transportation, and fluid resuscitation. The management of burn disasters highlights important points, including disaster plans, communication, transportation, facilities and staff. Pre-hospital care is well explained but has an unusual heading and layout, that is the management of pain, tetanus immunization and prevention of hypothermia and also gastrointestinal problems are included under one title "Decompression of stomach"! The description of fluid resuscitation is of limited use to the British doctor as it is primarily "American" fluid resuscitation with a brief mention of colloids and no mention of the Muir and Barclay formula, the mainstay of British burn resuscitation. I enjoyed reading the chapter on the pathophysiology of burn shock and burn oedema but unfortunately some of this is repeated under fluid resuscitation and early management.

The third section aims to concentrate on the "Burn wound". This section again suffers from problems of a multi-author book in that there are several repetitions, including that of tables. There is a very brief chapter on anaesthesia for burned patients. A proportion of this includes inhalation injury, a subject which is also covered in three chapters of the next section entitled "Inhalational injury".

The fifth section is on "Responses to injury". This is the largest section and covers a wide range of topics. These include nutritional needs and support, multiple organ failure and its treatment, pathophysiological changes in burns, burn nursing and burns in the elderly and children. It has some good chapters but is a mixture of very different topics. I am not sure if "Responses to injury" is the correct title or if it should have been divided into more than one section. The chapter on renal failure in burned patients should perhaps be incorporated into that on critical care of burn complications as there is a significant amount of overlap in these two chapters.

The sixth section covers non-thermal injuries such as electrical, cold, chemical and radiation injuries, and exfoliative disorders and necrotizing soft tissue infection. These were well written and interesting to read.

The final three sections are on rehabilitation, reconstruction and psychological and social issues. After reading the earlier chapter on anaesthesia for burned patients, I had hoped that anaesthesia for reconstructive surgery would be covered in the section on reconstruction. Unfortunately, this topic has been overlooked and needs to be addressed as it presents anaesthetic problems different from those of the acute phase. Pain response and pain control are covered in the section entitled psychological and social issues. I feel that this chapter, although well written, is misplaced. It gives the impression that pain management is more a long-term problem rather than an early priority in the acute management of burns.

This book has aimed to provide an overall view of total burn management and in so doing has covered a wide range of topics. Most of the chapters are well written but as with all multi-author books, the standard of chapters varies. Anaesthesia does not appear to have been well represented. I believe that the chapters could have been grouped differently to make it an easier reference book. Perhaps the chapters on anaesthesia should have been grouped together to make a better impact. All chapters are well referenced. The summary at the end of each chapter is useful and well done in some sections. The book however, reflects North American practice in many areas, some of which are critical and cannot be easily overlooked by British doctors looking after burned patients. This multi-author book also suffers from a great deal of repetition and will be useful as a reference book, but probably more for surgeons than anaesthetists.

EDITORIAL

Transoesophageal echocardiography in anaesthesia and intensive care

Transoesophageal echocardiography (TOE) is becoming an increasingly important diagnostic tool in anaesthesia and intensive care. The oesophagus lies immediately posterior to the heart and great vessels and, unlike transthoracic ultrasound, provides an imaging window without interference from intervening structures. Because of this proximity, TOE can use high frequency 5-MHz probes which provide much higher resolution images than those that can be obtained with conventional 2.5–3-MHz transthoracic probes. The uses of TOE have been classified into five main categories [1]:

(1) Imaging of structures which may be inadequately displayed by transthoracic echocardiography, such as the left atrial appendage and the descending thoracic aorta, or when the presence of a prosthetic valve produces an ultrasound shadow.

(2) Diagnosis of conditions in which the superior image quality is vital, for example assessment of endocarditis, intracardiac thrombus, valvular malfunction or aortic dissection. In aortic dissection, TOE has been reported in experienced hands to have a diagnostic sensitivity and specificity of more than 95% [2]. An emerging indication is the routine use of TOE to exclude the presence of left atrial thrombus before elective cardioversion for atrial fibrillation [3].

(3) Ultrasound examination of patients with conditions such as obesity or emphysema which prevent image clarity with transthoracic techniques.

(4) Intraoperative use in both cardiac and non-cardiac surgery to monitor such variables as left ventricular wall motion, effectiveness of valve repair and presence of air embolism without disturbing the surgical field.

(5) Use in the intensive care unit to aid diagnostic conundrums unresolved by other techniques.

The technique was first used in 1976 using a rigid device but standard technology now comprises a biplane probe mounted on a flexible, steerable endoscope imaging in both horizontal and transverse planes, with spectral and colour flow Doppler. Newer multiplane probes allow scanning at any angle through 180°. The technique is invasive, usually carried out under sedation and appears remarkably safe. The overall complication rate is of the order of a fraction of 1% in most series [1]. In one large study group of more than 10000 diagnostic cases, there was one fatality (bleeding tumour infiltrating the oesophagus) and 18 cardiac, pulmonary or bleeding complications [4]. This safety record contrasts markedly with that of gastrointestinal endoscopy [5], perhaps because patients are monitored more intensively and the danger of cardiorespiratory complications are readily apparent. The principal contraindications to TOE are oesophageal tumours, stenoses, diverticulae or varices. Transient bacteraemia has been reported after TOE but antibiotic prophylaxis against endocarditis is currently considered unnecessary.

The TOE probe can be maintained in a stable position allowing beat-by-beat monitoring of cardiac function over prolonged periods. Cardiac output can be measured by Doppler interrogation of aortic blood flow, assessment of preload can be obtained by measurement of left ventricular diastolic dimension and of afterload by calculation of end-systolic wall stress, as described by Greim, Roewer and Esch [6]. Contractility can be assessed by measurement of shortening fraction and ejection fraction, although the dependence of such measures on loading conditions and the geometrical assumptions made with calculation of ejection fraction imply that such measures are of limited value. Determination of the end-systolic left ventricular diameter–pressure relationship in a manner analogous to the pressure–volume relationship may be a better echo-derived index of ventricular function [7].

The ability of TOE to image clearly the endocardial surface allows the technique to be used to monitor global and regional ventricular function in both cardiac and non-cardiac surgical patients in an attempt to detect the occurrence of myocardial ischaemia. Regional wall motion abnormalities occur within seconds of the onset of myocardial ischaemia [8], well before the occurrence of ECG changes or chest pain. Studies in high risk patients have confirmed that TOE is a more sensitive indicator of perioperative myocardial ischaemia than the ECG or haemodynamic monitoring [9, 10]. Whether or not this increased ability to detect perioperative ischaemia results in improved patient outcome is unknown. Compared with preoperative clinical evaluation and standard ECG monitoring, intraoperative TOE failed to add significantly to the ability to identify patients with adverse outcomes caused by myocardial ischaemia [11]. A limitation to monitoring myocardial ischaemia by TOE is that continuous monitoring is usually performed in only one plane and may fail to detect ischaemia in other segments. More importantly, detection of wall movement abnormalities is made by eye so that considerable experience is necessary in image interpretation. This is a particular problem when there are pre-existing wall motion abnormalities, a common feature of patients with ischaemic heart disease. Automated edge detection techniques and the use of cine loops and split screens to allow image comparison may help to overcome such problems. On-line analysis packages are being developed which give continuous information on both measured and derived haemodynamic indices.

The increasing use of mitral and tricuspid valve repair rather than replacement in cases of valvular incompetence has made detailed knowledge of valvular anatomy important in the preoperative assessment of such patients. A TOE study performed before operation or on the operating table before cardiopulmonary bypass allows the surgeon to plan appropriate operative strategies to deal with annular dilatation, cusp retraction, prolapse or perforation. Intraoperative TOE performed after mitral valve repair has been found to identify accurately both satisfactory repairs and those cases with significant residual regurgitation requiring surgical revision [12, 13]. However, assessment of the severity of mitral regurgitation by echo Doppler study is unsatisfactory because colour flow Doppler mapping displays velocity, not total regurgitant flow, and certainly does not provide an "ultrasonic angiogram". The tendency of eccentric regurgitant jets to wrap around the circumference of the left atrium makes underestimation of their severity a common problem. Again, because of the lack of hard numerical data and derived indices, considerable experience in signal interpretation is necessary. Numerous other cardiac surgical procedures have been reported in which intraoperative TOE has been helpful, including myectomy for hypertrophic cardiomyopathy, resection of membranous subaortic stenosis and pulmonary artery and vein anastomosis during lung transplantation.

Although not all editorial writers have been enthusiastic about intraoperative TOE [14–16] and have emphasized the dangers of increased complications and the potential for misdiagnoses, there seems to be a growing acceptance of its value, particularly in valve reconstruction. If TOE is to be brought into routine use as an intra- and postoperative monitoring procedure or in the assessment on the operating table of the results of valvular surgery, two important difficulties arise. The first is the ready availability of equipment, as and when it is needed, and the second is the presence of a well trained operator to interpret the results. The costs of providing an intraoperative TOE service are hard to estimate. A TOE probe alone currently costs in the region of £30000 (and has a limited life span of approximately 500 procedures) and an echo Doppler system approximately £100000. The set-up costs of a dedicated intraoperative unit are consequently substantial, yet sharing time on machines which are in heavy demand for routine diagnostic use inevitably implies that they may be unavailable when required.

Because of their clarity, TOE signals are much easier to interpret than those from transthoracic probes, but nevertheless correct training is essential. To date in the UK, TOE has been largely the preserve of cardiologists but it is impractical to expect them to provide an on-demand intraoperative service. For anaesthetists or surgeons to undertake the responsibility of image interpretation requires an addendum to their normal training programmes. Furthermore, when trained, skills need to be practised to be retained. At present there are no UK guidelines even for the training of cardiologists in TOE but the American Society of Echocardiography published its recommendations in 1992 [17]. Recent preliminary data from Yale indicate that it is not possible during a 3-month cardiac anaesthesia rotation to acquire the standard of skill necessary for independent practice [18]. Although it is recognized that specialized training in TOE for anaesthetists is essential, it is currently difficult to know how it would be best achieved or what numbers and type of case mixed will be required. As with so many things in the UK, success with the technique is likely to come from a small group of enthusiasts who have the energy to raise the money for equipment and the commitment to train correctly, probably in their own time.

The impressive image quality obtainable with TOE and the relative ease with which it can be performed make it likely that it will become an increasingly important diagnostic and monitoring tool during surgery and in the intensive care unit. However, as with any imaging technique, the results obtained will only be as good as the quality of interpretation and this implies appropriate training and continued collaboration with cardiological colleagues, not "having a go" when it becomes a necessity. The potential for misdiagnosis with any imaging technique must never be forgotten.

CLINICAL INVESTIGATIONS

Single bolus compared with a fractionated dose injection technique of bupivacaine for extradural Caesarean section: effect on uteroplacental and fetal haemodynamic state

J. KARINEN, L. MÄKÄRÄINEN, S. ALAHUHTA, R. JOUPPILA AND P. JOUPPILA

Summary

We studied 26 healthy parturients undergoing elective Caesarean section, allocated randomly to receive extradural block with 0.5% plain bupivacaine in a double-blind manner in either a single bolus or fractionated doses. After a 3-ml test dose, an additional 20 ml of bupivacaine were given over a 5-min period in the single bolus group ($n = 13$) and over a 25-min period in the fractionated dose group ($n = 13$). We studied the effects of bupivacaine on blood flow velocities in the maternal placental and non-placental uterine and fetal umbilical arteries before and four times during establishment of extradural block using a pulsed colour Doppler technique. Median sensory block reached T3 in the single-dose group compared with T4 in the fractionated-dose group. Two subjects in each group required i.v. ephedrine to correct transient hypotension (systolic arterial pressure < 90 mm Hg). Blood flow velocity waveform indices of the uterine and umbilical arteries did not differ significantly within or between groups during the study. There was no significant difference in neonatal outcome, as assessed by Apgar scores and umbilical artery pH values. In conclusion, we observed no deterioration in uteroplacental circulation after administration of a single bolus dose of bupivacaine. (*Br. J. Anaesth.* 1996; **77**: 140–144)

Key words

Anaesthesia, obstetric. Blood, flow, feto–uteroplacental. Anaesthetic techniques, extradural. Anaesthetics local, bupivacaine.

Induction of extradural block with bupivacaine in fractionated doses is a routine technique for elective Caesarean section but it is slow in producing surgical anaesthesia for emergency cases. In order to speed up the onset of sensory block in such acute cases, the local anaesthetic has been given as a single bolus dose via either a needle [1] or catheter [2–4]. This technique may be advantageous, especially in mothers, who already have an extradural catheter *in situ* for pain relief during labour. In previous studies, 0.5% plain bupivacaine given as a slow bolus or in fractionated doses did not cause an increase in uteroplacental and fetal umbilical blood flow resistance [5–7]. In contrast, Alahuhta and colleagues [8] found increased uterine artery Doppler indices, possibly indicating increased vascular resistance, after administration of 20 ml of 0.5% plain bupivacaine as a bolus injection over a 5-min period. Injection of local anaesthetic in fractionated doses via the catheter appeared to be a safer and more efficient technique for extradural Caesarean section than a single dose [9]. In that study, the incidence of hypotension was significantly lower and, after birth, the efficacy of sensory block was greater in the fractionated-dose group than in the single-dose group, while there was no difference in the condition of the neonates, as assessed by Apgar score. Nevertheless, it has been shown that a single bolus dose of bupivacaine does not have any harmful effect on fetal and neonatal outcome, as evaluated by fetal heart rate patterns [10] and Apgar score [11, 12].

There are conflicting results of studies on the effects of extradural anaesthesia on maternal and uteroplacental haemodynamic state, partly because of different injection techniques and doses of local anaesthetics. Therefore, we have compared, in a double-blind, randomized study, the effects of a single bolus and fractionated doses of bupivacaine on maternal uterine and fetal umbilical artery blood flow velocity waveforms using a colour Doppler technique.

Patients and methods

We examined 26 healthy parturients at term (gestational weeks 37–40) undergoing elective Caesarean section because of breech presentation, fetopelvic disproportion or repeat Caesarean section. The study was approved by Oulu University Ethics Committee and informed written consent was obtained from each patient. None of the patients was in labour. Exclusion criteria included multiple gestation and maternal or fetal complications during pregnancy (e.g. pre-eclampsia, diabetes or signs of placental insufficiency).

Patients were given 30 ml of sodium citrate 0.3 mol $litre^{-1}$ orally, 30–60 min before entering the operating theatre, where they were monitored with a three-lead ECG, pulse oximetry and automated non-

invasive arterial pressure (Cardiocap, Datex, Finland). Oxygen 3 litre min^{-1} was administered via a nasal cannula. A peripheral vein was cannulated for administration of i.v. fluids. With the patient in a right lateral position, the extradural space was identified at the L2–3 or L3–4 interspace with an 18-gauge needle using the loss of resistance technique. A catheter was inserted 3 cm cephalad into the extradural space and secured after negative aspiration for blood and cerebrospinal fluid. Patients were then turned to the supine position with left lateral tilt. Local anaesthetic was not injected. Patients received a preload of Ringer's acetate solution 1 litre over a 15–20-min period. Immediately after preloading, the first Doppler ultrasound recording was performed.

The left and right maternal uterine (main branch) arteries near the cervix before their divisions and the fetal umbilical artery were identified by colour Doppler and blood velocity waveforms recorded by the pulsed Doppler method with a 3.75-MHz sector probe and 120-Hz high-pass filter. Peripheral arterial resistance was expressed in terms of pulsatility index (PI), calculated as PI = (systolic peak velocity − end-diastolic velocity)/mean velocity during cardiac cycle, and measured from the blood velocity waveform profile (the average of three consecutive waveforms).

After the first Doppler recording, patients were allocated randomly to one of two groups of 13 to receive 0.5% plain bupivacaine in a double-blind design, either as a single bolus or in fractionated doses. Randomization was performed in the operating theatre using sealed envelopes. A test dose of bupivacaine 3 ml was injected via the catheter. After 4 min, if there were no signs of subarachnoid or i.v. injection, patients in the single-dose group received a 20-ml (100 mg) bolus dose of bupivacaine over 5 min, and those in the fractionated-dose group an 8-ml (40 mg) dose diluted with 0.9% saline 12 ml (i.e. 20 ml in all) over 5 min. Then, in the latter group, additional bupivacaine doses of 8 ml (40 mg) and 4 ml (20 mg) over 1 min were given 15 and 20 min from the first dose, respectively. In the single-dose group, equal volumes of 0.9% saline were administered in a similar manner. Thus the total amount of bupivacaine given was identical in both groups (23 ml (115 mg)). A Doppler measurement of the same arteries was repeated 5 and 10 min after the first injection of bupivacaine (the second and third Doppler recording) and then 4 min after the subsequent two injections of either bupivacaine or saline (the fourth and fifth Doppler recording). The obstetrician (L. M.) who performed all Doppler recordings and the author (J. K.) who administered all extradural blocks were blinded to the anaesthetic solutions used in the study. The level of sensory block was assessed before surgery, and if below T5, bupivacaine 3–5 ml was given via the catheter.

Maternal heart rate (HR) was monitored continuously and systolic arterial pressure (SAP) recorded every 2 min during the study. During establishment of extradural block, an infusion of a second litre of Ringer's acetate solution was started in both groups to maintain maternal arterial pressure. Hypotension, defined as a decrease in SAP to less than 100 mm Hg or to 80% of baseline, was treated by increasing the rate of crystalloid infusion. If a value of < 90 mm Hg was recorded, ephedrine 5–10 mg was given i.v. The time from uterine incision to delivery was recorded. After delivery, a paediatrician evaluated Apgar scores at 1 and 5 min, and blood samples from a double-clamped umbilical artery were obtained immediately for measurement of acid–base status. The paediatrician also was unaware of the method of bupivacaine injection used for extradural block.

Student's *t* test was used to detect differences in baseline values between the groups. Analysis of variance for repeated measures was used to assess the statistical significance of the differences in maternal haemodynamic variables (HR, SAP and PI) between and within groups. The Greenhouse–Geisser adjustment for multi-sampler asphericity was used to avoid excessive type I error [13]. Values for maternal SAP were computed as percentage changes from baseline values for later analysis. The number of 11 subjects in each group was determined previously to be sufficient to detect, with 80% power and a 5% significance level, a difference of 30% in mean uterine artery PI between the groups [14]. The difference of 30% in the PI values was considered clinically significant. The Mann–Whitney *U* test was used to analyse differences in the height of sensory block between groups. Differences were considered significant if $P < 0.05$. Values are presented as mean (SD, 95% confidence interval (CI) or range) where appropriate.

Results

There was no significant difference in basic clinical data between the groups except for maternal weight. Despite randomization, mothers in the fractionated-dose group weighed significantly more than mothers in the other group (table 1). Changes in mean maternal HR did not differ between ($P = 0.12$) or within ($P = 0.45$) groups during the study (table 2). Similarly, changes in mean maternal SAP did not differ between groups ($P = 0.39$). Mean SAP decreased to a minimum of 86 (95% CI 78–93)% of baseline, that is from 127 (122–132) to 109 (98–119) mm Hg ($P = 0.002$) in the fractionated-dose group, and to 85 (79–92)%, that is from 128 (123–134) to 106 (98–114) mm Hg ($P = 0.001$) in the single-dose group (fig. 1). The lowest values of SAP in each group were observed within 10–20 min after induction of extradural block. In total, hypotension (SAP < 100 mm Hg) occurred in six of 26 patients (23%) (three patients in each group). Of these six subjects, two in each group developed more severe but transient hypotension with SAP < 90 mm Hg, and required ephedrine 5–10 mg i.v. All four patients also required atropine 0.5 mg i.v. for transient bradycardia with HR $\leqslant$ 50 beat min^{-1}. Total requirement for ephedrine was 20 mg in the single-dose and 30 mg in the fractionated-dose group.

Comparison between the right and left uterine arteries showed no difference in PI. Therefore, mean PI from these two vessels was calculated in each

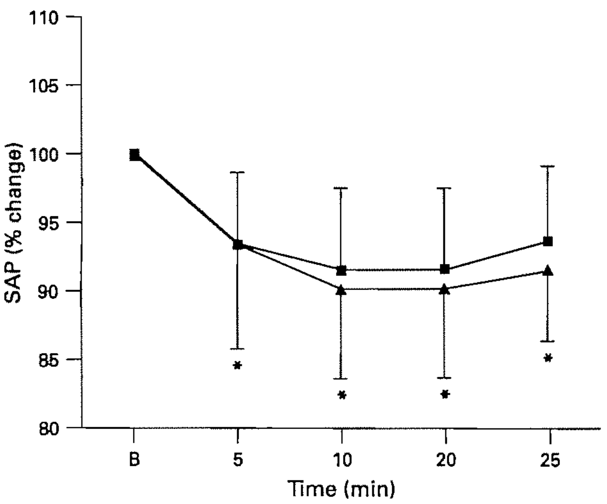

Figure 1 Mean (95 % CI) percentage changes in maternal systolic arterial pressure (SAP) during the study. SAP decreased significantly in both groups after induction of extradural anaesthesia (* $P < 0.05$). B = Before extradural anaesthesia. Time = minutes after the first dose of bupivacaine. There were no significant differences between the single-dose (▲) and fractionated-dose (■) groups.

patient and used for later analysis. Administration of ephedrine and atropine did not result in any significant changes in individual uterine and umbilical artery PI, and therefore all PI values were included in the subsequent analysis. Changes in mean PI values for uterine and umbilical arteries were not significant within or between groups (table 3). One neonate in the fractionated-dose group had an Apgar score of 7 at 1 min. Apgar scores at 5 min were ≥ 8 and pH values in the umbilical artery ≥ 7.17 (range 7.17–7.42) in all neonates in both groups (table 1). Sensory block was adequate for surgery in both groups. One patient in the fractionated-dose group required i.v. opioid (alfentanil) because of visceral pain during surgery. Median level of sensory block was T3 (range T2–5) in the single-dose group and T4 (T3–5) in the other group. This difference, although statistically significant ($P = 0.021$), was clinically irrelevant.

Discussion

Basic mean uterine and umbilical artery PI values observed in this study were in accord with previous findings in uncomplicated late pregnancies [15–18]. We did not measure PI before preloading as earlier studies have shown no difference in PI measured before and after preloading [7, 19, 20]. Under the conditions of this study, a total dose of 23 ml (115 mg) of 0.5 % bupivacaine, given either as a single bolus or in fractionated doses via the extradural catheter, did not have any significant effect on maternal uterine and fetal umbilical artery PI, reflecting only minor changes in vascular resistance in these vessels. Other studies have also shown similar results after administration of 0.5 % plain bupivacaine in fractionated doses [5, 6]. In those two studies, only one ultrasound recording was obtained after induction of extradural block, either when sensory block was at T5 [5] or at 40 min [6]. In this study, Doppler recordings were performed repeatedly four times during establishment of extradural block. We were therefore able to also observe any transient changes in blood flow velocities and indices in these arteries. Giles, Lah and Trudinger [21] performed Doppler ultrasound measurements after preload and again at 15 and 30 min after extradural anaesthesia and observed a decrease in mean uteroplacental and fetal umbilical blood flow resistance in eight healthy parturients. In their opinion, the decrease in flow resistance reflected improved perfusion after maternal plasma volume expansion and extradural block. Patients in that study were examined in a semi-sitting (20°) position, however, which may possibly explain the difference in uteroplacental perfusion, as that position may lead to altered responses in maternal circulation (e.g. venous return) compared with that in the supine position during extradural block.

In contrast, Baumann and colleagues [16] observed an increase in uteroplacental PI after extradural anaesthesia, suggesting impairment of the uteroplacental circulation. In that study, a second ultrasound recording was obtained only once at 15 min after administration of two doses of 0.5% plain bupivacaine (7 ml each) preceded by a 3-ml test dose of 2% lignocaine with adrenaline. The dose of bupivacaine (14 ml) given before Doppler measurement was smaller than usual, and the increased resistance of the uteroplacental circulation was thought to be caused by decreased peripheral vascular resistance resulting in increased blood flow to the legs and subsequently a decrease in uteroplacental perfusion pressure. Alahuhta and colleagues [8] compared the effects of a single injection of 20 ml of 0.5% plain bupivacaine and 0.5% ropivacaine on uteroplacental and fetal circulation and found a significant increase in placental and non-placental uterine artery PI, 5 min after administration of bupivacaine and when sensory block was at T6–T4. In that study, a potential explanation for the increase in uterine artery PI after a bolus dose was a high bupivacaine concentration which caused vasoconstriction in the uterine arteries. In this study, bupivacaine was diluted with saline, however, and so the resulting concentration of local anaesthetic solution was probably lower than that in the former study [8]. The possible difference in concentrations may be one reason why we did not observe such an increase in PI after administration of bupivacaine. Thus it seems that there is variation between the results of several studies with regard to the effects of bupivacaine on vascular resistance in the uterine arteries. It is possible that the varied anaesthetic techniques and timings of Doppler measurements used in other studies [5, 6, 8, 16, 21] may hinder interpretation and comparison of the different results obtained.

Both groups in this study were almost comparable except for difference in weight and the level of sensory block achieved. These differences were clinically insignificant, however, and did not endanger the reliability of the comparison of Doppler measurements between the groups. We found similar changes in maternal heart rate and systolic arterial pressure after administration of bupivacaine with both techniques. Maternal hypotension occurred to a similar extent in both groups and the total incidence of hypotension (23%) observed was comparable with that reported in previous studies using a single bolus dose of bupivacaine [1, 2, 8, 20]. Recently, Griffin and Reynolds [12] reported a high incidence of hypotension after injection of a 20-ml bolus of either 0.5% bupivacaine or 0.5% ropivacaine, that is 83% (29/35) and 76% (28/37), respectively. In that study, however, patients were preloaded with only 500 ml of Hartmann's solution before extradural block, while in studies with preloading volumes of crystalloid solution greater than 1 litre, a lower incidence of hypotension was observed [1, 8, 20]. However, a recent study showed the ineffectiveness of preloading in preventing maternal hypotension caused by spinal anaesthesia for Caesarean delivery [22]. Another possible explanation for the high incidence of hypotension observed by Griffin and Reynolds [12] may be a more rapid onset of sympathetic block after administration of 17 ml of local anaesthetic over 4 min.

In previous studies, maternal and fetal plasma concentrations of bupivacaine measured after administration of a 20-ml bolus were less than toxic concentrations [4, 10, 23, 24] and there was no change in the heart rate pattern of healthy fetuses [10]. An extradural injection of local anaesthetic may still result in toxic maternal and fetal plasma concentrations or total spinal anaesthesia because of accidental intravascular or intrathecal injection. Therefore, local anaesthetics must be given with care in order to avoid these potential and acute life-threatening complications. Neonatal outcome, as assessed by 5-min Apgar scores and umbilical artery pH values, was uneventful in this study and in accord with other studies using a single bolus of local anaesthetic for extradural Caesarean section [1, 8, 10].

Spinal anaesthesia with 0.25% hyperbaric bupivacaine for Caesarean section: effects of volume

C. J. CHUNG, S. H. BAE, K. Y. CHAE AND Y. J. CHIN

Summary

To investigate the safety and efficacy of 0.25% hyperbaric bupivacaine for spinal anaesthesia in Caesarean section, we studied 60 parturients allocated randomly to one of three groups. According to the patient's height, groups 1, 2 and 3 received 3.2–3.6 ml (8–9 mg), 3.6–4.0 ml (9–10 mg) and 4.0–4.4 ml (10–11 mg) of 0.25% bupivacaine in 5% glucose, respectively. Subarachnoid injection was performed in the right lateral decubitus position, and parturients were then turned immediately supine with left uterine displacement. Mean spread of sensory analgesia was significantly higher in group 3 (T2–3) than in groups 1 and 2 (T4–5 in each group). Duration of sensory analgesia was significantly longer in groups 2 and 3 than in group 1. Complete motor block of the lower extremities occurred in all patients but in only one in group 1. Onset time and duration of motor block were not significantly different between the three groups. The incidence of hypotension was significantly higher in group 3 (75%) than in groups 1 and 2 (40% in each group). The efficacy of intraoperative analgesia was significantly greater in groups 2 and 3 than in group 1. The incidence of patients requiring analgesics during operation was significantly lower in groups 2 (25%) and 3(10%) than in group 1 (70%). There was no difference in neonatal condition between the three groups. Spinal anaesthesia with 3.6–4.0 ml of 0.25% bupivacaine in 5% glucose was satisfactory for Caesarean section. (*Br. J. Anaesth.* 1996; **77**: 145–149)

Key words

Anaesthetics local, bupivacaine. Anaesthetic techniques, subarachnoid. Anaesthesia, obstetric.

Amylocaine is a drug used frequently for spinal anaesthesia in Caesarean section. However, this agent often fails to provide good maternal sensory block [1, 2]. Recently, bupivacaine has gained popularity in obstetric anaesthesia but 0.5% plain bupivacaine has been shown to be unreliable and produced occasional high block [3, 4]. Therefore, hyperbaric bupivacaine has been used more often than plain bupivacaine for spinal anaesthesia in Caesarean section.

The total dose of bupivacaine is more important than volume or concentration of anaesthetic solution in determining spread of anaesthetic solution in the CSF [5–7]. However, the effect of volume of hyperbaric spinal anaesthetic solution injected may be additive to the effects of gravity, position and dose [8–10]. Almost all parturients given 0.5% hyperbaric bupivacaine 7.5–10 mg for spinal anaesthesia in Caesarean section required supplementary analgesia because of visceral pain during surgery [11, 12]. When hyperbaric bupivacaine 10–15 mg was used for spinal anaesthesia in Caesarean section, good sensory block developed and the incidence of supplementary analgesia was decreased [2, 12]. However, the volume exceeded 3 ml in those cases. When 0.25% hyperbaric bupivacaine solution 10–15 mg is used for spinal anaesthesia in Caesarean section, the volume reaches 4–6 ml, which may influence spinal anaesthesia because of easily cephalad spread of local anaesthetic solution in CSF.

The aim of this investigation was to assess the safety and efficacy of 0.25% bupivacaine in 5% glucose for spinal anaesthesia in Caesarean section. Sensory and motor block, haemodynamic changes, quality of intraoperative analgesia and complications were compared.

Patients and methods

We studied 60 term parturients, ASA I or II, chosen to have spinal anaesthesia for elective Caesarean section. The study was approved by the Hospital Ethics Committee and written informed consent was obtained from all patients at the preoperative visit. Parturients who had obstetric complications or evidence of fetal compromise were excluded. Hyperbaric bupivacaine solution 0.25% was made with the same volume of 0.5% bupivacaine hydrochloride (Marcaine, Astra, Sweden) and 10% glucose monohydrate (Daehan Pharmaceutical Co., Seoul, Korea). The specific gravity of 0.25% bupivacaine in 5% glucose was 1.022 at 23 °C. Patients were allocated randomly to one of three groups. Each group had 10 mothers who were 156–160 cm tall and 10 mothers 161–165 cm tall. Group 1 mothers (156–160 cm tall) were given 3.2 ml of 0.25% bupivacaine in 5% glucose, and those 161–165 cm received 3.6 ml.

CHAN JONG CHUNG*, MD, SEUNG HWAN BAE, MD, KI YOUNG CHAE, MD, YOUNG JHOON CHIN, MD, Department of Anesthesiology, College of Medicine, Dong-A University, Pusan, Korea. Accepted for publication: March 13, 1996.

In groups 2 and 3, the corresponding bupivacaine volumes were 3.6 and 4.0 ml, and 4.0 and 4.4 ml, respectively. All subarachnoid blocks were performed by one anaesthetist and data were collected by two registrars who were blinded to the solutions used.

All parturients received ranitidine 10 mg and glycopyrronium 0.2 mg i.m., 1 h before arrival in the operating room. All patients received an infusion of lactated Ringer's solution 1000 ml over 10–20 min before induction. They were also given ephedrine 40 mg i.m., approximately 10 min before subarachnoid injection. Subarachnoid injection was performed in the right lateral decubitus position with a 25-gauge Quincke spinal needle, using a midline approach at the L2–3 or L3–4 interspace. The predetermined volume of local anaesthetic was injected over 20–30 s without barbotage. After subarachnoid injection, mothers were immediately turned supine with left uterine displacement. The parturient's head was rested on a pillow.

The spread of sensory block to pinprick was measured at 2-min intervals during the first 10 min and then at 5-min intervals. The degree of motor block of the lower extremities was also assessed at the same interval, using the modified Bromage scale: 0 = no paralysis; 1 = unable to raise the extended leg; 2 = unable to flex knee; 3 = unable to flex ankle. Maternal arterial pressure and heart rate were recorded every minute until delivery and every 5 min thereafter, using an automated, non-invasive device (Sirecust 404, Simens, Germany). If hypotension (systolic arterial pressure less than 100 mm Hg or a 20% reduction in systolic arterial pressure) occurred, it was treated promptly by increasing uterine displacement and the rate of fluid administration. If hypotension persisted despite these measures, ephedrine 10 mg was given i.v. and repeated as needed. Oxygen was administered routinely by face mask at 6 litre min^{-1} until the end of operation. When sensory block at or above T6 was established, surgery were commenced. The incidence and frequency of complications were noted.

The efficacy of intraoperative analgesia was assessed by the following four categories: excellent = no discomfort during the procedure; good = mild discomfort but required no systemic analgesia; fair = pain that required additional analgesia; and poor = moderate or severe pain that needed more than fentanyl 100 µg or general anaesthesia.

When the patient complained of pain, fentanyl 50 µg was given i.v. and repeated as needed. I.v. midazolam 2.5 mg was administered if the patient requested to sleep after the birth of the baby. I.v. droperidol 0.625 mg was used to treat nausea or vomiting. The times of bupivacaine injection, start of surgery, delivery and termination of surgery were recorded. The condition of the neonates was assessed by Apgar score at 1 and 5 min after delivery. All mothers received oxytocin by continuous infusion after delivery. Return of sensory and motor function was assessed at 15-min intervals until complete recovery from anaesthesia.

All data are expressed as number or mean (SD or range). The results were analysed using one-way and two-way ANOVA followed by Tukey's test for parametric data, and the chi-square test with Yates' correction, the Kruskall-Wallis followed by the Mann–Whitney *U* test for non-parametric data. $P < 0.05$ was considered statistically significant.

Results

There were no statistically significant differences in mean age, weight, height and gestational age between the three groups (table 1). In four patients in group 1, the spinal was converted to general anaesthesia 10–15 min after delivery of the neonate because surgical anaesthesia was inadequate. These patients were excluded from further analysis of sensory and motor block.

Onset and segmental spread of sensory analgesia are shown in figure 1. Cephalad spread of sensory analgesia was increased significantly with an increase in volume, and the differences between groups 1 and 3 and between groups 2 and 3 were significant. Onset time of sensory analgesia to T6 was significantly faster in group 3 than in group 1. The mean maximal level of analgesia in group 3 (T2–3) was significantly higher than that in groups 1 and 2 (T4–5 in each), and the times to achieve the maximal level were similar, with an average of 10–15 min between the three groups. Sensory analgesia at or above T6 was obtained in all patients, but sensory analgesia below

Category	Group 1 ($n = 20$)	Group 2* ($n = 20$)	Group 3* ($n = 20$)
Excellent	4	10	16
Good	2	5	2
Fair	9	5	2
Poor	5	0	0

T4 was obtained significantly more in group 1 (70 %) than in groups 2 and 3 (30 % and 10 %, respectively). Two patients in group 3 had a block up to C6 and C7, respectively. Total time for regression of sensory analgesia to T10 and L5 was significantly longer in groups 2 and 3 than in group 1 (table 2).

Complete motor block of the lower extremities was obtained in all patients at an average time of 10–13 min, except for one patient in group 1 (Bromage scale 2). Duration of complete motor block was longer with an increase in volume, but this was not statistically significant (table 2).

There were no significant differences in systolic arterial pressure and heart rate during the first 30 min between the three groups (figs 2, 3). Compared with control preanaesthetic values, systolic arterial pressure was significantly decreased at 4 min in groups 1 and 2, and at 4 and 6 min in group 3. The percentage maximal decreases in systolic arterial pressure were 16.1 (9.9) %, 17.8 (10.1) % and 25.7 (13.2) % in groups 1, 2 and 3, respectively, recorded 4–6 min after induction of spinal anaesthesia. Hypotension developed in eight of 20 patients in group 1 (40 %), and six required i.v. ephedrine, compared with eight of 20 patients in group 2 (40 %), and seven required i.v. ephedrine and 15 of 20 patients in group 3 (75 %), and 14 required i.v. ephedrine. The incidence of hypotension and need for ephedrine were significantly greater in group 3 than in groups 1 and 2.

The various time intervals from induction of anaesthesia to end of surgery are shown in table 3. There were no significant differences in these times between the groups.

No patient in any group complained of discomfort at incision from skin to the uterus. The efficacy of intraoperative analgesia was significantly greater in groups 2 and 3 than in group 1 (table 4). In group 1, only four patients (20 %) were totally painless; 14 patients (70 %) required supplementary analgesia 40–50 min after induction, four of whom required general anaesthesia about 10–15 min after delivery. Five patients in group 2 (25 %) and two in group 3 (10 %) required supplementary analgesia 50–60 min after induction of spinal anaesthesia.

Neonatal weight and Apgar scores at 1 and 5 min were similar between the three groups (table 5). The condition of the neonates was good. Two infants in group 3 had an Apgar score of 5 and 6, but more than 8 at 5 min.

Table 5 Neonatal status (mean (SD))

	Group 1 ($n = 20$)	Group 2 ($n = 20$)	Group 3 ($n = 20$)
Neonatal weight (kg)	3.3 (0.3)	3.2 (0.2)	3.4 (0.3)
Apgar score			
1 min	8.3 (0.5)	8.4 (0.5)	8.2 (0.8)
5 min	9.5 (0.4)	9.6 (0.3)	9.4 (0.7)

Table 6 Intraoperative complications (number). †Patients in whom droperidol was used. *$P < 0.05$ *vs* groups 1 and 2

	Group 1 ($n = 20$)	Group 2 ($n = 20$)	Group 3 ($n = 20$)
Hypotension	8	8	15*
Bradycardia	4	5	7
Nausea/vomiting†	2	3	6
Dyspnoea	1	2	4
Transient headache	0	0	2

The incidences of complications after spinal anaesthesia are shown in table 6. Complications occurred more in group 3 than in groups 1 and 2, but this was not significant.

Discussion

Our data indicated that 0.25% bupivacaine in 5% glucose could be used safely and effectively for spinal anaesthesia in Caesarean section. Lignocaine, amylocaine and bupivacaine can be used for spinal anaesthesia in Caesarean section but some mothers who received amylocaine spinal anaesthesia needed supplementary analgesia because of intraoperative visceral pain [1, 2]. Recently, bupivacaine has gained popularity in obstetric anaesthesia for extradural and also spinal anaesthesia. Hyperbaric bupivacaine provided better intraoperative analgesia and produced shorter duration of motor block than hyperbaric amylocaine [2].

Within the range of 7.5–12 mg of 0.5% hyperbaric bupivacaine, similar levels of sensory block to T3 occurred, despite the varying doses of drug injected, but the duration of sensory block was longer with the large than the small dose. Increasing the dose increased the intensity of motor block, but the duration of motor block was similar [11, 12]. In our study, increasing the dose increased the level and duration of sensory block, but the intensity and duration of motor block were similar between the three groups.

Several reports [5–7] have suggested that the total dose of bupivacaine is more important than volume or concentration of anaesthetic solution in determining spread of anaesthetic solution in the CSF. The relationship between volume of anaesthetic injected for spinal anaesthesia and final level of block have not been defined clearly. Baricity determines primarily the spread of subarachnoid local anaesthetic in the CSF. In recent studies of plain spinal infusion in pregnancy, final levels of block were similar with volumes and concentrations ranging from 3 ml of 0.5% to 18 ml of 0.083% plain bupivacaine [13–15]. However, increasing the volume administered into the subarachnoid space, especially in a hyperbaric solution, resulted in significantly greater cephalad spread [8–10]. The effect of volume of hyperbaric spinal anaesthetic solution injected may be additive to the effects of gravity, position and dose. High volumes of hyperbaric local anaesthetic solution may influence the spread of local anaesthetic in CSF and final block. In the clinical dose range (10–15 mg) of 0.5% or 0.75% hyperbaric bupivacaine, the volume does not exceed 3 ml. When 0.25% hyperbaric bupivacaine solution is used, the dose of 10–15 mg reaches 3.0–6.0 ml. The large volume itself may influence the spread of local anaesthetic in CSF and final block, especially in the narrow subarachnoid space of term parturients. In our preliminary study with 5–6 ml of 0.25% bupivacaine in 5% glucose, sensory block occurred at the cervical level of dermatome in a few minutes after subarachnoid injection in all parturients. Severe hypotension developed and nausea or vomiting, dyspnoea, and transient headache occurred in all patients.

The one cause limiting the choice of spinal anaesthesia for Caesarean section is the possibility of neonatal depression because of severe hypotension after spinal anaesthesia. Petersen and co-workers [12] reported incidences of hypotension in patients given 7.5–10 mg and 10–12.5 mg of 0.5% hyperbaric bupivacaine solution of 24% and 26%, respectively. In our study, despite adequate hydration and i.m. ephedrine before induction of spinal anaesthesia, the incidence of hypotension in the 4.0–4.4-ml group (75%) was significantly greater than in the 3.2–3.6-ml and 3.6–4.0-ml groups (40% in each group). The percentage maximal decrease in systolic arterial pressure and the incidence of patients requiring supplementary ephedrine were significantly greater in the 4.0–4.4-ml group than in the two other groups. The condition of the neonates, assessed by Apgar score, was good and similar in the three groups. Two neonates in the 4.0–4.4-ml group had an Apgar score of 5 and 6 at 1 min, respectively, but the scores at 5 min were more than 8. In these two neonates, maternal systolic arterial pressure decreased transiently to 70 and 75 mm Hg a few minutes after induction of spinal anaesthesia. A large volume of 0.25% hyperbaric bupivacaine solution could easily spread in a cephalad direction in CSF and influence sensory block and also sympathetic block. Therefore, simply increasing the volume of 0.25% hyperbaric bupivacaine solution to increase the dose must be considered for spinal anaesthesia for Caesarean section.

It is generally accepted that sensory analgesia to at least the fourth thoracic dermatome is necessary for Caesarean section. However, despite seemingly adequate levels of sensory block regardless of the local anaesthetic used, many parturients required supplementary analgesia during exteriorization of the uterus and traction on the abdominal viscera [11, 12]. In our study, all parturients experienced a block at or above T6 in sensory analgesia. Sensory block above T4 was obtained significantly more often in the 3.6–4.0-ml and 4.0–4.4-ml groups than in the 3.2–3.6-ml group. No patient complained of discomfort at incision from skin to the uterus. Petersen and co-workers [12] reported that similar spread of sensory block to above T3 developed in patients who received 7.5–10 mg and 10–12.5 mg of 0.5 % hyperbaric bupivacaine solution, but the use of a larger dose of bupivacaine resulted in a lesser frequency of moderate to severe visceral pain. In our study, the frequency of visceral pain and requirement for supplementary opioids were significantly less in the 3.6–4.0-ml and 4.0–4.4-ml groups than in the 3.2–3.6-ml group.

A variety of ways have been tried to improve the quality of spinal anaesthesia during Caesarean section. Injecting larger doses of local anaesthetic can improve the quality of sensory block [12, 16]. In 0.25 % hyperbaric bupivacaine solution, increasing volume to increase the dose is not recommended because the large volume itself would cause cervical spinal block and severe hypotension. The addition of adrenaline [17], morphine [18] or fentanyl [19] to hyperbaric bupivacaine solution improved the quality of bupivacaine intraoperative analgesia. In our study with 0.25 % hyperbaric bupivacaine, a larger dose improved the quality of sensory analgesia, but the incidence of hypotension and its severity were greater with volumes exceeding 4.0 ml.

Spinal anaesthesia for Caesarean section: effect of Sprotte needle orientation

K. S. JAMES, S. M. STOTT, E. M. MCGRADY, F. J. PEARSALL, W. T. FRAME AND D. RUSSELL

Summary

We induced spinal anaesthesia in 100 women presenting for elective Caesarean section with the mother in the right lateral position. Patients were allocated randomly to have the side eye of the 24-gauge Sprotte spinal needle pointing in one of four directions: group A, cephalad; group B, right lateral; group C, left lateral; group D, caudad. Isobaric bupivacaine 0.5% (2.5 ml) was injected over 30 s before the mother was placed supine with a 15° left lateral tilt. Onset time and height of the subsequent analgesic and anaesthetic blocks were assessed by a blinded observer. Onset of sensory block to T4 was significantly faster in group A ($P = 0.001$). There were no differences in final block height, incidence of hypotension, nausea and vomiting or ephedrine requirements. (*Br. J. Anaesth.* 1996; **77**: 150–152)

Key words

Anaesthesia, obstetric. Anaesthetics local, bupivacaine. Anaesthetic techniques, subarachnoid. Equipment, needles.

Spinal anaesthesia for Caesarean section avoids the maternal and fetal risks of general anaesthesia. Side effects associated with spinal anaesthesia include hypotension, nausea and post-dural puncture headache, all of which are more common in the parturient [1].

The incidence of post-spinal headache may be reduced by the use of pencil-point needles which have a lateral eye near the tip of the needle from which local anaesthetic emerges at an angle to the longitudinal line of the needle [2, 3]. This can be manipulated to produce "directional anaesthesia" in which spread of local anaesthetic solution in the cerebrospinal fluid (CSF) is affected by the direction in which the eye of the needle faces [4]. This may be a way of ensuring adequate sensory block for surgery when a single injection spinal technique is used.

Directional spinal anaesthesia using a needle with a side lumen was first described by Kirschner in 1932 [5]. Orientation of the eye of the 22-gauge Whitacre spinal needle has been shown to affect sensory block height in both obstetric [6] and general surgical patients [4]. When the eye of the needle faced caudad rather than cephalad, maximum height of sensory block was lower in general surgical patients [7]. It has been shown that solutions injected through a Whitacre needle exit at a 90° angle to the longitudinal axis of the needle [4]. The Sprotte needle has a larger eye than the Whitacre needle; it is not known if local anaesthetic leaves the Sprotte needle at the same angle as from the Whitacre needle.

The aim of this study was to assess if the direction in which the eye of the Sprotte needle faces during injection of local anaesthetic solution affects the onset of sensory block for Caesarean section and the incidence of side effects.

Patients and methods

We studied 100 women undergoing elective Caesarean section with spinal anaesthesia, at 38–42 weeks' gestation, with a singleton pregnancy. Mothers less than 150 cm or more than 170 cm in height, or with babies displaying evidence of fetal compromise, or with oligo- or polyhydramnios were excluded. The study was approved by the hospital Ethics Committee and all patients gave written informed consent.

Mothers received a preload of crystalloid solution 15 ml kg^{-1} and were then placed in the right lateral position. Spinal anaesthesia was induced with isobaric bupivacaine 2.5 ml via a 24-gauge Sprotte needle at the L2–3 intervertebral space. Patients were allocated randomly to have the lateral eye of the needle facing in one of four directions: a = cephalad, b = right lateral, c = left lateral or d = caudad.

When free flow of cerebrospinal fluid had been confirmed, 0.5% isobaric bupivacaine 2.5 ml was injected over 30 s and the woman placed immediately supine with a 15° left lateral tilt. The subsequent sensory block was assessed using loss of cold

sensation to ice by one of the authors, who was unaware of the direction of the needle eye; the first assessment was made 3 min after injection of local anaesthetic and then at 2-min intervals until sensory block stopped increasing.

When loss of cold sensation had reached the fourth thoracic dermatomal level, sensory block was assessed with a 25-gauge needle for the anaesthetic level (no sensation to pinprick) and analgesic level (aware of pinprick but does not feel sharp). At this time the extent of sacral block was assessed.

Non-invasive arterial pressure was measured at 2-min intervals. A reduction in systolic pressure to < 70 % of the pre-spinal value or nausea, or both, was treated with ephedrine i.v. Administration of anti-emetics was recorded. Discomfort during Caesarean section was treated with increments of alfentanil 0.25 mg i.v. All mothers were reviewed after operation and their satisfaction with the technique assessed using a 10-cm visual analogue score (VAS).

A power calculation determined that a sample size of 80 women would be required to demonstrate a 2.5-min difference in onset time of sensory block if the SD of onset time was 2.8 min (calculated from an earlier pilot study). This gave the study 80 % power; an additional 20 women were studied in the event that study violations excluded women from analysis. Data were analysed using the Kruskal–Wallis test followed by the Mann–Whitney *U* test and chi-square test as appropriate (statistics package Minitab for windows version 9.2).

Results

Patient data were comparable (table 1).

ONSET OF SENSORY BLOCK

The Kruskal–Wallis test showed a significant difference between groups; onset of sensory block to T4 measured by loss of cold sensation was faster when the eye of the Sprotte needle faced cephalad (group A) ($P = 0.001$). Mann–Whitney comparison showed that group A had a significantly faster onset of sensory block than all other groups (group B, $P = 0.0112$, group C, $P = 0.0035$ and group D, $P = 0.014$). There were no significant differences between groups B, C and D in onset time. Median onset times ranged from 5 min in group A to 8 min in group D (table 2).

Table 2 Time to development of suitable block for surgery (loss of cold sensation). Kruskal–Wallis, $P = 0.001$

	Group			
Onset time to T4 (min)	A	B	C	D
Median (interquartile range)	5.0 (3.0–5.0)	7.0 (5.0–9.0)	6.0 (5.0–8.5)	8.0 (5.0–9.0)

Table 3 Maximum block height (loss of cold sensation) (number of patients at each level). No significant differences (chi-square)

	Group			
	A	B	C	D
< T4	0	0	0	0
T4–T3	8	11	11	14
⩾ T2	16	13	13	10

Table 4 Anaesthetic and analgesic levels to pinprick when loss of cold sensation was at T4 (median (interquartile range)). No significant differences (Kruskal–Wallis)

	A	B	C	D
Anaesthetic block	T6 (7–6)	T7 (8–6)	T7 (7–6)	T7 (8–6)
Min–max block height	T8–T5	T9–T5	T9–T5	T10–T5
Analgesic block	T5 (5–5)	T5 (6–5)	T6 (6–5)	T5 (6–5)
Min–max block height	T6–T4	T7–T4	T7–T4	T8–T4

All women developed adequate sensory block for surgery and there was no difference in final block height achieved between the groups, with maximum block height of T4–C6 (table 3). Although more women in the cephalad group developed sensory block above T1 (four patients compared with one each in both lateral groups and none in the caudad group) this was not significant. None of the women with a high block complained of respiratory symptoms. All mothers had satisfactory sacral block by the time sensory block had reached T4.

The median difference between anaesthetic and analgesic sensory levels, measured immediately before skin incision, was two dermatomes in all groups. Similarly, the median difference between analgesic and loss of cold sensation levels was two dermatomes. The maximum difference between anaesthetic and loss of cold sensation levels was six dermatomes (table 4).

	A ($n = 24$)	B ($n = 24$)	C ($n = 24$)	D ($n = 24$)
Antiemetics	6	5	4	7
Alfentanil	3	5	4	3
Ephedrine	21	15	15	18
VAS for satisfaction (median (IQ))	9.5 (8.7–9.9)	9.5 (8.3–9.9)	9.75 (9.5–10)	9.55 (8.6–9.8)

HYPOTENSION

The incidence of hypotension (a reduction in systolic pressure to < 70 % of pre-spinal value) was high in all groups. There was no significant difference in the number of women requiring ephedrine or in the total dose they received. The incidence of nausea and antiemetic requirements was similar (table 5).

MATERNAL SATISFACTION

Small numbers of women in each group required supplementary analgesia at some time during operation and i.v. alfentanil was given (table 5). Upper levels of sensory block for those who did and did not require alfentanil were comparable. Maternal satisfaction with spinal anaesthesia, assessed by VAS, was high, regardless of Sprotte needle orientation or intraoperative analgesic requirements (table 5).

No woman in the study developed post-dural puncture headache.

Discussion

We found that if the eye of a 24-gauge Sprotte needle faced cephalad during induction of spinal anaesthesia for Caesarean section, onset of sensory block was significantly faster than if it pointed caudad or laterally. Onset of sensory block was slowest when the needle eye faced caudad, although this was not significant. Although the difference in onset time was small (median 5 min in group A and 8 min in group D), it may be important when anaesthesia is required for emergency Caesarean section when a rapid onset of spinal anaesthesia may avoid general anaesthesia with its associated risks.

All women developed adequate sensory block for surgery, regardless of needle orientation. As maximum sensory block height was comparable in all groups, the distributions of local anaesthetic within the CSF were probably similar.

For elective Caesarean section when the onset time of sensory block is less important, orientation of the Sprotte needle is probably irrelevant. However, this contrasts with a previous study in which it was found that spinal injection in the caudad direction failed to provide reliable anaesthesia for Caesarean section; 80 % of women required adjunctive measures (e.g. Trendelenburg position) [6]. The method used in this study was different as a smaller volume (2 ml) of hyperbaric amethocaine (in 10 % glucose) was injected at the L3–4 intervertebral space over a shorter time interval of 15 s. We cannot conclude from our study that anaesthesia would be adequate if spinal injection was made in the sitting position or if hyperbaric bupivacaine was used.

Although onset of sensory block was faster in group A, there was no corresponding increase in the incidence of hypotension or in ephedrine or antiemetic requirements. This contrasts with an earlier study in which it was demonstrated that more ephedrine was required when there was rapid onset of sensory block [8]. More women in the cephalad group had sensory levels (loss of cold sensation) above T1; none had respiratory difficulties.

A total of 15.6 % of women required i.v. alfentanil for discomfort during operation, usually when the peritoneum was handled towards the end of surgery. The maximum dose given was 0.5 mg (incrementally) and requirements were comparable between groups. Satisfaction scores were excellent in all groups. It is unclear why women experience pain during Caesarean section despite apparently adequate regional anaesthesia. It has been suggested that if spinal opioids are not used, an anaesthetic block to T5 is required to prevent pain during Caesarean section under spinal anaesthesia [9]. While the anaesthetic level was below T5 in the majority of women (81 %) at the start of surgery in our study the level probably increased further during surgery, although this was not measured. Our study confirmed that there is an area of differential sensory block at the upper end of a spinal anaesthetic, as described by Russell [9]. In general, anaesthetic levels are two dermatomes lower than analgesic levels, which are two dermatomes lower than loss of cold sensation levels. Confirmation of an adequate anaesthetic level is essential as the maximum difference between anaesthetic and cold sensation levels was six dermatomes when loss of cold sensation was measured at T4 before surgery.

Soft tissue anatomy within the vertebral canal in pregnant women

Y. HIRABAYASHI, R. SHIMIZU, H. FUKUDA, K. SAITOH AND T. IGARASHI

Summary

To clarify pregnancy-induced changes in soft tissue anatomy within the vertebral canal, we have studied magnetic resonance (MR) images of the lumbar spine in three women. In each subject, T2-weighted axial MR images were obtained both before pregnancy and at 32 weeks' gestation, and the paired images were compared. The extradural venous plexus was engorged significantly in supine parturients. In addition, the engorged extradural venous plexus displaced the dura away from the wall of the vertebral canal in a posterior direction, which resulted in a decrease in the volume of the cerebrospinal fluid in the dural sac. These findings confirmed the long-held concept that the engorged extradural venous plexus in supine parturients decreases the effective capacity of the extradural and subarachnoid spaces. (*Br. J. Anaesth.* 1996; **77**: 153–156)

Key words

Anatomy, extradural space. Anaesthesia, obstetric. Pregnancy. Measurement techniques, magnetic resonance imaging.

Obstruction of the inferior vena cava by the enlarged pregnant uterus impairs the return of venous blood from the legs and pelvis to the heart [1, 2]. The collateral circulation includes the intraosseous vertebral veins, paravertebral veins and extradural venous plexus. Of these, the engorged extradural venous plexus is expected to decrease the effective capacity of the extradural and subarachnoid spaces [3–5], and parturients may require less anaesthetic agent for induction of extradural or spinal anaesthesia.

Although the engorged extradural venous plexus during pregnancy has been demonstrated well by radiological studies of the inferior vena cava [1, 2, 5], few objective data are available to confirm the decrease in the capacity of the extradural and subarachnoid spaces. Magnetic resonance (MR) imaging provides detailed information on soft tissue anatomy within the vertebral canal [6, 7]. To clarify pregnancy-induced changes in soft tissue anatomy within the vertebral canal, we performed MR imaging both before and during pregnancy in volunteers.

Subjects and methods

The Institutional Review Board approved our study and informed consent was obtained from three women aged 28, 30 and 31 yr. MR imaging examinations were performed twice in each subject: before pregnancy (non-pregnant) and at 32 weeks' gestation (pregnancy). All MR images were obtained with the subject supine and with the legs extended. T2-weighted axial MR images of the second and third lumbar vertebrae were obtained using an MR imaging system (MRT-200/FXIII super version, Toshiba Corporation, Tokyo, Japan) operating at 1.5 T with a single surface coil. Technical specifications included a repetition time of 3000 ms, echo time of 112 ms, slice thickness of 4 mm, number of slices of 9 and a field of view of 15 cm. On each slice level, we compared the paired images (non-pregnant *vs* pregnancy) with each other in the same subject. Measurements obtained from MR images included the following: maximum distance between the anterior surface of the ligamentum flavum and the dura; area of the fat-filled posterior extradural space at the level of the intervertebral disc between the second and third lumbar vertebrae; and area of the dual sac at the level of the intervertebral disc between the second and third lumbar vertebrae. The areas were measured using a digital planimeter (KP-90N, Uchida Yoko, Ltd, Tokyo, Japan).

Results

ANATOMY IN NON-PREGNANT STATE

The extradural space around the dura varied in shape and size depending on the longitudinal site of the axial slices. At the level of the intervertebral disc, the anterior extradural space was absent as the annular ligament of the disc was in direct contact wtih the dural sac (fig. 1A). The fat-filled posterior extradural space which was enclosed by the ligamentum flavum, the articular capsule and the dura was present posteriorly. The fat in this space, appearing as a triangle, had a high signal and was uniform (white). The lateral and posterior extradural spaces were discontinuous, separated by areas of contact of the dura with the ligamentum flavum. At the level of the pedicles, virtually no contents were identified in the extradural space except veins anteriorly (fig. 2A). At the level of the lamina, the extradural space, which contained nerve roots, vessels and fat, opened up lateral to the dura (fig. 3A).

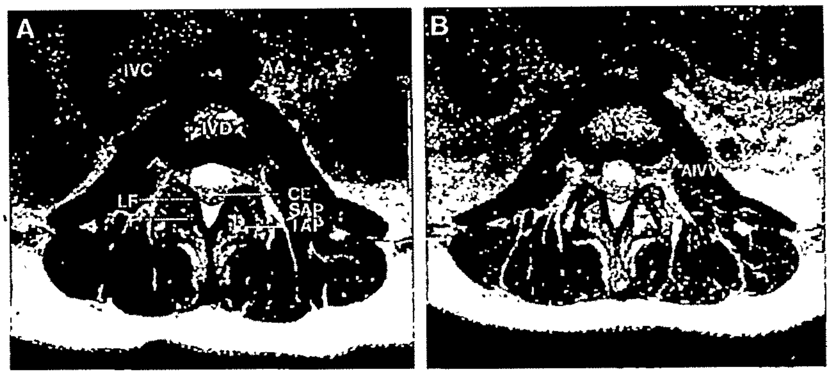

Figure 1 T2-weighted MR images showing an axial section through the L2–3 intervertebral disc before pregnancy (A) and at 32 weeks' gestation (B). AA = Abdominal aorta, IVC = inferior vena cava, IVD = intervertebral disc, CE = cauda equina, SAP = superior articular process, IAP = inferior articular process, LF = ligamentum flavum, F = posteromedial extradural fat, AIVV = anterior internal vertebral vein. The anterior extradural space is absent as the annular ligament of the disc is in direct contact with the dural sac. During pregnancy, the anterior vertebral veins are engorged, particularly on both sides of the extradural space. The fat-filled posterior extradural space which is enclosed by the ligamentum flavum, the articular capsule and the dura remains unchanged during pregnancy. The fat in this space, appearing as a triangle, has a high signal and is uniform (white).

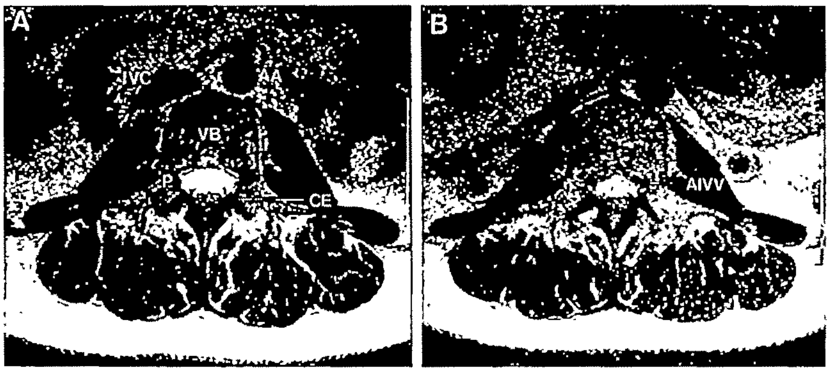

Figure 2 T2-weighted MR images showing an axial section at the level of the pedicles of L3 before pregnancy (A) and at 32 weeks' gestation (B). AA = Abdominal aorta, IVC = inferior vena cava, VB = vertebral body, P = pedicle, CE = cauda equina, AIVV = anterior internal vertebral vein. Virtually no contents are identified in the extradural space except veins anteriorly before pregnancy (A). The anterior vertebral veins are substantially engorged during pregnancy (B).

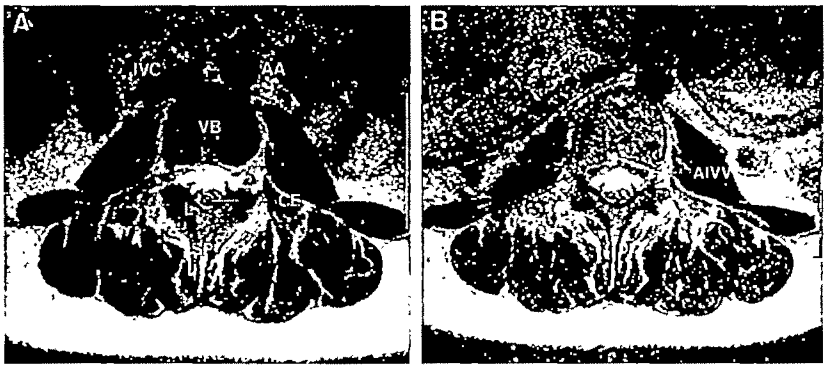

Figure 3 T2-weighted MR images showing an axial section at the level of the lamina of L3 before pregnancy (A) and at 32 weeks' gestation (B). AA = Abdominal aorta, IVC = inferior vena cava, VB = vertebral body, L = lamina, SP = spinous process, CE = cauda equina, AIVV = anterior internal vertebral vein. The engorged anterior internal vertebral veins displace the dura away from the wall of the vertebral canal in a posterior direction (B).

CHANGES IN ANATOMY DURING PREGNANCY

With the parturient supine, the enlarged pregnant uterus pressed down the abdominal aorta and inferior vena cava against the vertebral body. In particular, the inferior vena cava was almost totally obstructed (figs 1B, 2B and 3B). The extradural venous plexus was substantially engorged. The engorgement was noted in the anterior vertebral veins (figs 1B, 2B and 3B). The engorged anterior vertebral veins displaced

the dura away from the wall of the vertebral canal in a posterior direction (figs 2B and 3B), which resulted in a decrease in the volume of cerebrospinal fluid in the dural sac. The fat-filled posterior extradural space remained unchanged during pregnancy (fig. 1B). Measurements obtained are documented in table 1.

Discussion

Injection of a given dose of local anaesthetics into the extradural space or subarachnoid space produces more extensive segmental block in late pregnancy than at other times [3–5, 8]. Possible explanations for this increased sensitivity to regional anaesthesia include anatomical and hormonal changes associated with pregnancy [9–14].

The dural sac is enclosed completely by the rigid vertebral canal and tissues of the central nervous system are incompressible. Because the volume of the intradural contents remains unchanged, the volumes of blood and CSF within the vertebral canal must vary in inverse relationship to each other [5]. In the later stages of pregnancy the gravid uterus compresses both the inferior vena cava and abdominal aorta, whenever the gravida lies in the supine position [1, 2, 15]. Obstruction of the inferior vena cava diverts a proportion of the venous return from the legs and pelvic structure into the vertebral venous system, which is composed of three freely communicating valveless networks: intraosseous vertebral veins, paravertebral veins and the extradural venous plexus [16]. Of these, the engorged extradural venous plexus is expected to decrease the effective capacity of the extradural [3] and subarachnoid spaces [4, 5]. These decreased spaces are considered to be one of the reasons for pregnancy-induced enhancement of regional anaesthesia.

Examination of the soft tissue anatomy within the vertebral canal has been performed by radiographic methods such as extradurography [17], extradural venography [16, 18], myelography [5] and computed tomography [19]. Because these radiographic examinations include fetal hazards for exposure to x-rays, changes in soft tissue anatomy during pregnancy have not been investigated fully, although they are traditionally considered to influence significantly the spread of regional anaesthesia in parturients. In contrast with radiographic examinations, MR imaging, without the use of x-rays, provides detailed information on soft tissue anatomy within the vertebral canal [6, 7]. The signal intensity of circulating blood is extremely low on T2-weighted MR images, and hence not only large vessels but also small vessels can be identified without the use of contrast media. The intensity of CSF in the adjacent dural sac appears slightly higher than that of extradural fat. Thus T2-weighted MR images provided quantitative data on the effective capacity of the extradural and subarachnoid spaces.

The extradural venous plexus was engorged significantly in our supine parturients. In addition, the engorged extradural venous plexus displaced the dura away from the wall of the vertebral canal in a posterior direction, which resulted in a decrease in the volume of cerebrospinal fluid in the dural sac. These findings confirm the long-held concept that the engorged extradural venous plexus in supine parturients decreases the effective capacity of the extradural and subarachnoid spaces [3–5], and parturients may therefore require less anaesthetic agent for induction of extradural or spinal anaesthesia.

A surprising finding was that the fat-filled posterior extradural space remained unchanged during pregnancy, although the anterior and lateral extradural space significantly altered its feature. The extradural venous plexus is composed of two vertical channels, the anterior vertebral veins that course the length of the vertebral canal, hugging the backs of the vertebral bodies and intervertebral discs [16]. The anterior vertebral veins, consisting of medial and lateral components, lie medial to the pedicles and bulge laterally as they cross the intervertebral disc spaces. The findings observed in the MR images of our parturients were consistent with engorgement of the anterior vertebral veins. On the other hand, there is increasing evidence to indicate that the posterior vertebral veins are rudimentary or do not exist [16, 18, 20, 21], although anatomy texts always describe such a system [22–27]. Indeed, a review of 1200 lumbar extradural venograms demonstrated that the posterior vertebral veins were not seen during venography [16]. Failure of the posterior extradural space to alter during pregnancy probably confirms the absence of a system of posterior vertebral veins.

The number of subjects examined in this study was small. Within-subject comparison, however, made it possible to demonstrate clearly the pregnancy-induced changes in soft tissue anatomy within the vertebral canal in the later stages of pregnancy. In addition, we have demonstrated occlusion of the inferior vena cava in the supine position at 32 weeks' gestation. This supports the recommendation that pregnant women, especially during the later stages of pregnancy, should never be allowed to adopt the supine position, although our parturients did not complain of any discomfort during the examination.

Thrombelastography changes in pre-eclampsia and eclampsia

C. E. P. ORLIKOWSKI, D. A. ROCKE, W. B. MURRAY, E. GOUWS, J. MOODLEY,
D. G. KENOYER AND S. BYRNE

Summary

We have measured platelet count, bleeding time and thrombelastography (TEG) variables and the correlation between these variables in 49 pregnant patients presenting with pre-eclampsia or eclampsia. Eighteen patients (37%) had a platelet count $\leqslant 150 \times 10^9$ litre^{-1} and seven (14%) had a platelet count $\leqslant 100 \times 10^9$ litre^{-1}. Bleeding time was prolonged > 9.5 min in 13 (27%) patients and the TEG was abnormal in four (8%). The TEG variables, k time and maximum amplitude (MA) had a strong correlation with platelet count (k time–platelet count $\leqslant 150 \times 10^9$ litre^{-1}, $r = -0.68$, $P = 0.003$, platelet count $\leqslant 100 \times 10^9$ litre^{-1}, $r = -0.84$, $P = 0.02$; MA–platelet count $\leqslant 150 \times 10^9$ litre^{-1}, $r = 0.72$, $P = 0.001$, platelet count $\leqslant 100 \times 10^9$ litre^{-1}, $r = 0.78$, $P = 0.04$). There was no correlation between bleeding time and thrombocytopenia (platelet count $\leqslant 150 \times 10^9$ litre^{-1}, $r = -0.18$, ns; platelet count $\leqslant 100 \times 10^9$ litre^{-1}, $r = 0.09$, ns). There was no correlation between bleeding time and any measured TEG variable. Of the 10 (20%) patients with an adequate platelet count ($> 100 \times 10^9$ litre^{-1}) but prolonged bleeding time, the TEG was normal, suggesting adequate haemostasis. An MA of 53 mm, which is the lower limit for normal pregnancy, correlated with a platelet count of 54×10^9 litre^{-1} (95% confidence limits 40–75×10^9 litre^{-1}). Although the number of patients with severe thrombocytopenia was small, a platelet count of 75×10^9 litre^{-1} should be associated with adequate haemostasis. (*Br. J. Anaesth.* 1996; **77**: 157–161)

Key words

Blood, coagulation. Measurement techniques, thrombelastography. Anaesthetic techniques, regional. Complications, pre-eclampsia.

Normal pregnancy is associated with an increased incidence of thrombocytopenia, with 6.6% of pregnant women presenting with platelet counts less than 150×10^9 litre^{-1} [1]. In addition, pre-eclampsia may complicate up to 12% of pregnancies and is often associated with abnormalities of haemostasis [2]. Although thrombocytopenia may occur in up to 50% of patients with severe disease [3], clotting factors are rarely affected [4]. Platelet dysfunction may also be present as tests of platelet aggregation [5] and bleeding times may be abnormal [6], despite adequate platelet numbers. Parturients also frequently require extradural anaesthesia and despite the ready availability of platelet counts and coagulation tests, the lower limit of platelet count at which safe regional anaesthesia can be performed is unclear. In addition, the relevance of platelet dysfunction and the usefulness of the bleeding time are uncertain. Thus there is a need for a specific, sensitive and rapid bedside test of haemostasis [7].

The thrombelastograph (TEG) is an on-site monitor that measures all phases of coagulation to clot retraction [8]. Its usefulness, compared with standard laboratory tests of coagulation, has been described during liver transplantation [9] and after cardiopulmonary bypass [10]. TEG changes in normal pregnancy and labour [11–13], and in pre-eclampsia [14, 15] have been reported.

The aim of this study was first, to assess if the TEG could be used to detect haemostatic abnormalities in patients with pre-eclampsia or eclampsia, as demonstrated by abnormal platelet counts and standard laboratory tests of coagulation; second, to determine if a correlation existed between any TEG variable and platelet count to determine a platelet count at which TEG variables become abnormal, thus enabling some guidelines for a lower limit of platelet count at which regional anaesthesia should be avoided; and third, to use the TEG to assess overall haemostasis in a group of patients with normal platelet counts but prolonged bleeding times.

Patients and methods

Approval for the study was obtained from the Professional and Ethics Standards Sub-Committee of the Faculty of Medicine, University of Natal. Informed consent was obtained from all patients, except those with eclampsia. Patients presenting to the delivery suite with a diagnosis of pre-eclampsia

or eclampsia were entered into the study. Mild pre-eclampsia was defined as a systolic pressure > 140 mm Hg, diastolic > 90 mm Hg and proteinuria > 0.3 g litre^{-1} (1 or 2+ using dipstick measurement). Severe pre-eclampsia was diagnosed by one or more of the following criteria: systolic pressure > 160 mm Hg, diastolic pressure > 110 mm Hg or proteinuria > 5 g litre^{-1} (3 or 4+). The diagnosis of eclampsia was based on a documented history of a recent convulsion in any patient presenting with other features of pre-eclampsia without any previous history of epilepsy and in whom no other cause for convulsions could be determined. Patients with a history of bleeding disorders or recent ingestion of antiplatelet medication within the previous week were excluded.

After admission, arterial pressure was recorded and i.v. infusion of crystalloid started. Blood was sampled through a 19-gauge steel Butterfly needle using a three-syringe technique. The first sample was discarded, the second used for laboratory tests and the third sample used for TEG measurement. This last sample was obtained in a polypropylene syringe and transferred immediately to a polypropylene tube from which 0.36 ml of whole blood was pipetted into the prewarmed cuvette of a thrombelastograph (Thrombelastograph D, Helige, Freiburg in Breisgau). The TEG was situated in the delivery suite facilitating rapid commencement of measurement and was performed in a standard manner.

Bleeding time was measured using a modified Ivy technique with a disposable Simplate II (Organon, Durham) device on the lateral aspect of the volar surface of the forearm. Before incision a sphygmomanometer cuff was inflated to 40 mm Hg and blotting paper was used every 30 s to remove the blood without touching the edges of the incision. All bleeding time tests were performed by the same person (C.E.P.O.) and the TEG result was not available until completion of the bleeding time.

The following laboratory tests were obtained: haematology (haemoglobin, platelet count and mean platelet volume (mpv)), biochemistry (urea, creatinine, calcium, magnesium, albumin and uric acid), coagulation tests (prothrombin time (PT), activated partial thromboplastin time (APTT), thrombin time (TT) and clotting factors (fibrinogen, antithrombin III, protein C, factors V and VIII, and fibrin degradation products). Platelet counts were measured by automatic Coulter Counter.

Patients were studied as soon as possible after admission to the obstetric unit and choice of prophylaxis against or pharmacological control of convulsions and management of hypertension was the decision of the attending obstetrician.

Data were analysed using Pearson's correlation coefficients. Spearman's correlation was used if the groups were small ($n < 10$). Non-linear regression models were fitted to describe relationships between variables where appropriate. Patients were also evaluated further according to their platelet count: $\leqslant 150 \times 10^9$ litre^{-1} or $\leqslant 100 \times 10^9$ litre^{-1}. Values are expressed as mean (SD) and $P < 0.05$ was considered significant.

Results

We studied 49 patients over a 3-month period. The study group comprised seven patients with mild pre-eclampsia, 33 with severe pre-eclampsia and nine with eclampsia. Of the 49 patients, 18 (37%) had a platelet count $\leqslant 150 \times 10^9$ litre^{-1} and seven of these (14% of total) $\leqslant 100 \times 10^9$ litre^{-1}. Tests of coagulation (prolonged PT and reduced fibrinogen) were outside the normal range in two patients. In both of these patients, platelet count was less than 100×10^9 litre^{-1} and the TEG was abnormal. The TEG was abnormal in another two patients (total 8%), with MA reduced in all four. Three of these patients presented with the lowest platelet counts in the series (30, 36 and 59×10^9 litre^{-1}). The fourth patient had a platelet count of 286×10^9 litre^{-1}, normal PT, APTT and fibrinogen, normal bleeding time but mpv was 7.4 fl (normal range 7.4–10.4 fl). The patient with a platelet count of 30×10^9 litre^{-1} and reduced MA (43 mm) also had prolonged *r* (10.5 min) and *k* (6.0 min) times but normal PT, APTT and fibrinogen. In addition to the reduced MA, *k* time (5.5 min) was prolonged in another patient with a prolonged PT (13 s). Laboratory data, TEG variables and bleeding times are shown in table 1 and the number of patients with abnormal results according to platelet count are shown in table 2.

Table 1 Haematology and clotting results, TEG variables and bleeding times for all pre-eclamptic and eclamptic patients, and normal pregnancy values. Results are mean (SD). No significant differences between the two groups

Variable	Normal pregnancy	Term pre-eclampsia–eclampsia
Haematology

PC $\leqslant 100 \times 10^9$ litre^{-1} ($n = 7$)	−0.69 (0.08)	0.86 (0.01)
XDP		
All patients ($n = 49$)	0.54 (0.0001)	−0.52 (0.0001)
PC $\leqslant 150 \times 10^9$ litre^{-1} ($n = 18$)	0.57 (0.02)	−0.67 (0.003)

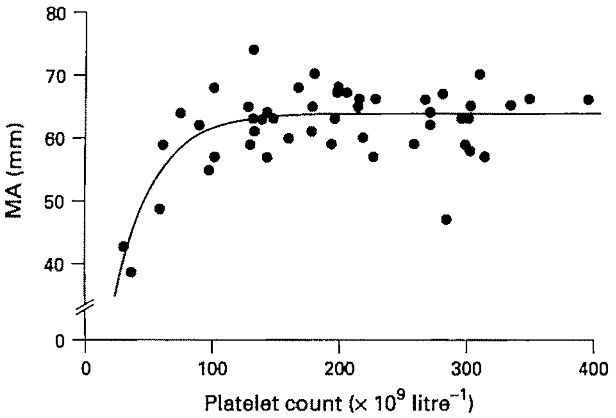

Figure 1 Scattergram of maximum amplitude (MA) of the thrombelastograph *vs* platelet count. The equation MA = 63.9 × (1 − exp (−0.033 platelets)) represents a negative exponential curve of best fit which has been calculated using a non-linear regression procedure.

Drug therapy (number of cases) at the time of evaluation included methyldopa (30), dihydralazine (22), nifedipine (8), diazepam (7), phenobarbitone (22), magnesium (10) and dexamethasone (8).

Correlation coefficients between platelet counts, fibrinogen and fibrin degradation products, and TEG variables, k time and MA, are shown in table 3; none of the above correlated with r time. There was no significant correlation between any TEG variable and PT, APTT, TT, factors V and VIII, antithrombin III, protein C, and serum concentration of urea, creatinine, calcium, magnesium and albumin.

There was a strong correlation between the TEG variables, k time and MA, and platelet count (k time–platelet count $\leqslant 150 \times 10^9$ litre^{-1}, $r = -0.68$, $P = 0.003$, platelet count $\leqslant 100 \times 10^9$ litre^{-1}, $r = -0.84$, $P = 0.02$; MA–platelet count $\leqslant 150 \times 10^9$ litre^{-1}, $r = 0.72$, $P = 0.001$, platelet count $\leqslant 100 \times 10^9$ litre^{-1}, $r = 0.78$, $P = 0.04$). Figure 1 shows a "hockey stick" relationship between MA and platelet count for all 49 patients. However, this relationship was linear for those seven patients with a platelet count $\leqslant 100 \times 10^9$ litre^{-1}. An MA of 53 mm, which is our lower limit for normal pregnancy (table 1), correlated with a platelet count of 54×10^9 litre^{-1} (95% confidence limits $40–75 \times 10^9$ litre^{-1}) (fig. 1). For all patients, there was a weak but significant negative correlation between bleeding time and platelet count ($r = -0.41$, $P = 0.003$), but no significant correlation in those patients with a platelet count $\leqslant 150 \times 10^9$ litre^{-1} or those with a platelet count $\leqslant 100 \times 10^9$ litre^{-1} ($r = -0.18$ and 0.09 respectively) (fig. 2). Bleeding time was prolonged in 13 (27%) patients. In those with a platelet count $> 100 \times 10^9$ litre^{-1}, 10 (20%) patients had prolonged bleeding times despite a normal TEG. There was no correlation between bleeding time and any TEG variable (r time $= -0.18$, k time $= 0.24$, MA $= -0.26$).

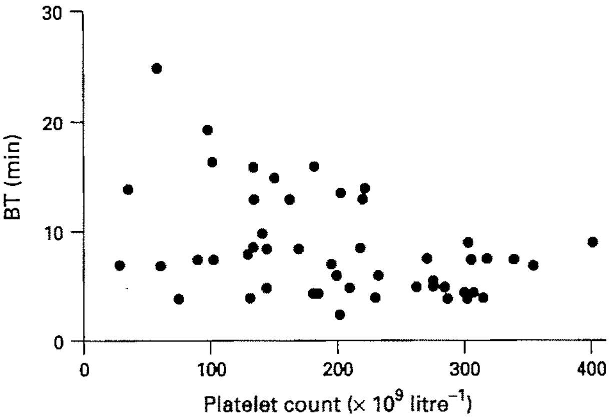

Figure 2 Scattergram of bleeding time (BT) *vs* platelet count. There was only a weak ($r = 0.41$, $P = 0.003$) correlation between the two variables.

Discussion

Platelet counts less than 150×10^9 litre^{-1} have been reported in 6.6% and less than 100×10^9 litre^{-1} in 1.2% of pregnant women in a study of more than 15000 deliveries [1]. The major causes were incidental thrombocytopenia of pregnancy (74%) and hypertensive diseases of pregnancy (21%). Severity of pre-eclampsia is an important determinant of the effect on platelets, with thrombocytopenia in up to 50% with severe disease [3]. Because coagulation factors are rarely reduced and only in the presence of thrombocytopenia, platelet count is a good screening test, with tests of coagulation reserved for those with reduced platelets [4]. These tests are generally available in most hospitals, but in practice time taken for these results to be available can vary enormously. However, the lower limit of platelet count at which regional anaesthesia can be performed safely is not clear, the importance of platelet dysfunction in pre-eclampsia is uncertain and the clinical relevance of bleeding time has been questioned [16]. Thus a machine that assesses haemostasis easily and rapidly in the delivery suite might not only be useful as a screening device but also may provide further information on overall clot formation in patients with reduced platelet counts or those at risk from platelet dysfunction.

The TEG is useful as it is compact, easily located within the delivery suite, relatively easy to use and produces initial results within 30 min.

The TEG measures whole blood clotting and the interaction between the protein coagulation cascade, fibrinogen and the platelet surface, from initiation of clotting to the final stages of clot lysis or retraction [8]. Thus the TEG has been found to be particularly useful during liver transplantation [9] and after cardiopulmonary bypass [10].

In normal pregnancy, reports of changes in the TEG are similar to normal values and are consistent with the hypercoagulable changes in pregnancy [12]. TEG changes of hypocoagulability have been described in a group of patients with severe pre-eclampsia, reduced platelet count and increased aspartate aminotransferase (AST) concentrations [14]. The TEG was used to diagnose and subsequently treat two episodes of haemorrhage in a patient with HELLP syndrome where conventional tests of coagulation were unhelpful [17]. Its use in three non-obstetric patients, with potential haemostatic abnormalities before regional anaesthesia, has also been described [18]. The TEG was used to assist risk of bleeding in a patient with idiopathic thrombocytopenic purpura with a reduced platelet count who underwent uneventful extradural anaesthesia [19].

In our small series, the TEG performed satisfactorily as a screening test compared with platelet count and laboratory tests of coagulation (PT, APTT and fibrinogen). MA was reduced in four patients. Three of these had the lowest platelet counts of the series. In the fourth patient, although platelet count appeared adequate, mean platelet volume (mpv) was 7.4 fl (normal pregnancy 7.4–10.4 fl). As mpv is increased in patients with pre-eclampsia [20], mpv was low for this patient. Platelet aggregation to ADP, collagen or adrenaline is directly proportional to platelet volume [21] and in thrombocytopenic patients, reduced mpv has been shown to be associated with an increased incidence of bleeding episodes [22]. As the TEG has been shown to correlate with platelet aggregation after cardiopulmonary bypass [23], the reduced MA is best explained by platelet dysfunction associated with smaller platelets.

Abnormalities of coagulation were rare in our study and in keeping with the findings of others that prolongation of the PT and APTT is seen only in those in whom platelet count is less than 100×10^9 litre^{-1} [4]. In our series, PT was slightly prolonged in two patients and associated with an abnormal TEG. TEG variables reflect the interdependence of platelets and clotting factors because the TEG is determined in whole blood, unlike laboratory tests which measure isolated aspects of coagulation in plasma. This is clearly illustrated in one patient with a platelet count of 30×10^9 litre^{-1} and reduced MA. Both r and k times were prolonged but PT and APTT were normal. Platelet phospholipid is necessary for the activation of factor X and prothrombin, and in the presence of a very low platelet count, the clotting cascade is affected, resulting in prolonged r and k times. In contrast, as phospholipid substitute is added during laboratory measurements, PT and APTT were normal. Our findings of a correlation between fibrin degradation products and MA and k are consistent with the documented inhibitory effects of fibrin degradation products on the conversion of fibrinogen to fibrin [24].

The 37 % incidence of thrombocytopenia (platelet count $< 150 \times 10^9$ litre^{-1}) in our patients with severe pre-eclampsia/eclampsia is similar to other studies: 34 % in a group of patients with severe disease [25] and 20 % in a group with both mild and severe disease [6]. Unfortunately, there are no clear guidelines in the literature on the safe level of platelet count at which extradural anaesthesia can be performed safely. In this study, none of the patients with a platelet count less than 100×10^9 litre^{-1}, a prolonged bleeding time or an abnormal TEG received a regional anaesthetic.

Anaesthetists are reluctant to perform an extradural block in patients with platelet counts less than 100×10^9 litre^{-1} [26], although a limit of 80×10^9 litre^{-1} has been suggested [27]. Our overall finding of a low correlation between TEG variables and platelet count has been reported previously in pregnant [12] and non-pregnant subjects [28]. This finding is not surprising as the TEG, by measuring overall clot strength, would be expected to remain relatively constant over a wide normal range of platelets. However, it is only when platelet numbers start to decrease to below a critical level that any linear relationship between TEG variables (k and MA) and platelet count is seen. Although the number of patients with a platelet count $< 100 \times 10^9$ litre^{-1} in our series was small, we have calculated that a platelet count of 54×10^9 litre^{-1} is associated with adequate TEG derived clot formation (95 % confidence limits $40–75 \times 10^9$ litre^{-1}). As the upper limit of our 95 % confidence interval for this relationship is a platelet count of 75×10^9 litre^{-1}, we conclude that patients with pre-eclampsia with platelet counts greater than this should not have regional anaesthesia denied to them. In another series of patients with severe pre-eclampsia, TEG was normal in three patients with a platelet count of $50–100 \times 10^9$ litre^{-1} [14]. Thus there is increasing evidence that regional anaesthesia is not contraindicated in patients with platelet counts as low as 75×10^9 litre^{-1}. At this time and because we do not have sufficient data, we cannot recommend that the TEG be used in isolation from an automated platelet count in deciding whether or not to use regional anaesthesia in a patient with severe pre-eclampsia. However, this is unlikely to happen because of the ready availability of automated platelet count machines. As more units obtain TEG machines we shall be able to assess more adequately the value of the TEG in conjunction with platelet count.

Bleeding time has been described to test for adequacy of haemostasis in those with reduced platelets [27, 29]. We found this test particularly unhelpful. One patient with a platelet count of 30×10^9 litre^{-1}, reduced fibrinogen, prolonged PT and abnormal TEG had a bleeding time of only 4 min. We were unable to demonstrate any correlation between platelets and bleeding time in those with a platelet count $< 100 \times 10^9$ litre^{-1}, in contrast with a study by Ramanathan and colleagues who reported a correlation of -0.76 in this group [6].

Platelet function is altered in pre-eclampsia and *in vitro* platelet aggregation may be reduced despite the presence of a normal platelet count [5]. Bleeding time has been used to test for this platelet defect and has been found to be prolonged in 34% of patients with severe pre-eclampsia and a platelet count > 100×10^9 litre^{-1} [6] and in 25% with a platelet count > 150×10^9 litre^{-1} [25]. In our patients with severe pre-eclampsia, 20% had a prolonged bleeding time in the presence of a platelet count > 100×10^9 litre^{-1}, yet the TEG was normal. The TEG is sensitive to qualitative abnormalities of platelets and a significant positive correlation between MA and platelet aggregation and collagen and adenosine diphosphate after cardiopulmonary bypass has been demonstrated [23]. Based on our findings, excluding these patients for regional anaesthesia is inappropriate.

Because *in vivo*, clotting occurs on cell surfaces rather than in plasma, the TEG performed on whole blood may provide a better indicator of the dynamics of clot formation than standard laboratory tests of coagulation which are measured in plasma. However, *in vivo*, haemostasis begins with platelet adhesion to the damaged vessel wall, and the TEG cannot measure this initial interaction between platelets and vascular endothelium. As a result, if the platelet defect is caused by interference with the normal interaction between platelets and vascular endothelium, then the TEG is unable to detect this effect, as occurs in uraemic patients or patients receiving aspirin [30]. Pre-eclampsia is associated with endothelial damage, impaired production of prostacycline and increased deposition of fibrin within the vascular bed. The TEG does not measure these local changes, but can be used to determine the effects on overall clotting associated with reduced platelet counts.

Alfentanil-mediated analgesia during propofol injection: no evidence for a peripheral action

I. J. WRENCH, K. J. GIRLING AND G. J. HOBBS

Summary

We have investigated if alfentanil acts via peripheral opioid receptors to relieve the pain which occurs on injection of propofol. Thirty seconds before induction of anaesthesia and immediately after a tourniquet at 50 mm Hg greater than systolic pressure was inflated on the upper arm, patients were given either placebo ($n = 22$), alfentanil 1 mg ($n = 22$) or lignocaine 40 mg ($n = 22$) via an i.v. cannula in the dorsum of the hand. Pain during injection of propofol was assessed using a three-point verbal rating scale, recorded at 8-s intervals. We found a significant reduction in pain after lignocaine compared with the two other groups ($P < 0.001$), but there was no difference between the placebo and alfentanil groups. We conclude that alfentanil does not relieve pain on injection with propofol via an action on peripheral opioid receptors when alfentanil is limited to the forearm for 30 s before induction of anaesthesia. (*Br. J. Anaesth.* 1996; **77**: 162–164)

Key words

Anaesthetics i.v., propofol. Analgesics opioid, alfentanil. Receptors, opioid. Pain, injection.

Recent work suggests that opioid analgesia may be mediated, at least in part, via peripheral opioid receptors [1]. Prior administration of alfentanil is known to reduce the pain that occurs after an injection of propofol [2]. In a recent study alfentanil was given 15 s before propofol [3]. Significant analgesia was demonstrated approximately 30 s after administration of alfentanil. This rapid onset of analgesic effect is inconsistent with other pharmacodynamic data [2, 4] for alfentanil. This may be explained by alfentanil acting, at least partially, on peripheral opioid receptors. In this double-blind, placebo-controlled study, we have further investigated this phenomenon by pretreatment with alfentanil in the presence of a tourniquet. We also compared the efficacy of alfentanil with lignocaine, an agent which acts locally to prevent propofol-induced pain [5].

Patients and methods

After obtaining Ethics Committee approval and informed consent, we studied 66 patients. Patients were ASA I–II, aged 18–65 yr, undergoing elective day-case surgery and were unpremedicated. After transfer to the anaesthetic room, non-invasive monitoring was commenced and a 22-gauge i.v. cannula sited in the dorsum of the non-dominant hand. Patients were allocated randomly using a sealed envelope technique to one of three groups ($n = 22$ in each group): group 1 received normal saline, group 2 alfentanil 1 mg and group 3 lignocaine 40 mg. A tourniquet was applied to the non-dominant arm, the cuff inflated to 50 mm Hg greater than systolic arterial pressure and the pretreatment dose injected in a total volume of 2 ml. All solutions were prepared by the same investigator (I.W.) who did not assess pain. Thirty seconds after the pretreatment bolus, the tourniquet was deflated and propofol 10 mg ml^{-1} was infused at a rate of 1200 ml h^{-1} using a Graseby 3400 infusion pump. Patients were then asked by a blinded second investigator (K.G.), to assess any discomfort in the arm below the level of the tourniquet at 8-s intervals using a three-point verbal rating scale (none, mild, severe) until loss of consciousness. The time taken to induce anaesthesia, and the volume of propofol required, were noted.

Statistical analysis was by ANOVA and chi-square, as appropriate, with $P < 0.05$ as significant. Previous work has indicated that alfentanil reduces the pain of injection of propofol by at least 50% [2]. On this basis 22 patients were needed in each group to confer a power of 0.9 at a P value of 0.05.

Results

The three groups were similar in age, weight and sex distribution, with no significant differences for duration of induction of anaesthesia. The dose of propofol given was significantly smaller in those who received alfentanil than in the two other groups (table 1).

Pain reported by patients in the three groups is shown in table 2. When considering the worst pain for each patient throughout the study, there was significantly less pain reported by patients who were given lignocaine before propofol compared with the two other groups ($P < 0.001$) (table 3). There was no difference in pain between patients who received alfentanil and placebo (table 3).

Discussion

The use of propofol for induction of anaesthesia is common and has been shown to be associated with pain in up to 84% of patients [3]. Many different factors have been associated with this phenomenon, including the temperature of the solution [6], size of the vein and speed of injection [7]. It has been shown that both lignocaine and alfentanil are effective in reducing the discomfort caused by propofol [2, 5] and that lignocaine has its maximum effect when given as pretreatment with a venous tourniquet occluding the proximal part of the arm [8].

Fletcher, Seavell and Bowen gave a bolus of alfentanil 15 s before induction of anaesthesia with propofol and showed a reduction in pain from 84% to 36% [3]. This difference started to become apparent 31 s after alfentanil has been given. This rapid onset of action conflicts with the published pharmacodynamic data of a half-time for access of alfentanil to the central biophase of 54 s [4] and a peak onset time of 90–120 s [2]. We designed this study to see if this discrepancy might be explained in part by alfentanil acting via peripheral opioid receptors to relieve the pain on injection of propofol. Peripheral opioid receptors have been identified in both animals and humans [9, 10]. Their physiological function is unclear, although it has been suggested that they may play a role in the inflammatory response [1] and recent work has suggested that both morphine and pethidine may relieve pain via peripheral opioid receptors when injected into the knee after arthroscopy [11].

In this study we were careful to control for cannula size and the temperature and rate of infusion of propofol. We included a group pretreated with lignocaine and a placebo group as we wished to compare the effects of an agent which is known to act locally, with any peripheral effect of alfentanil.

The incidence of pain in our saline and lignocaine groups supports the findings of a previous study where a venous tourniquet was used [8]. The combination of a tourniquet with lignocaine renders this a highly effective method for relieving the pain of injection of propofol, as Mangar and Holak demonstrated in their work. In our study, two patients in the lignocaine group complained of mild pain in the upper arm at 40 s (table 2) and it may be that to totally prevent pain it is necessary to use a larger volume of injection.

The statistically significant finding of reduced dose of propofol in the alfentanil group compared with those who received saline and lignocaine was not unexpected as Wall and Zacharias demonstrated a similar finding in their study [2]. Although not statistically significant, seven patients being asleep at 40 s in the alfentanil group compared with four in the lignocaine group and two in the saline group at the same time, makes our results more difficult to interpret, however, there are several interesting observations. The worst pain reported by patients receiving alfentanil confined to the forearm using an arterial tourniquet was comparable with those who received saline. This contrasts with the finding that alfentanil used without a tourniquet does relieve propofol pain [2, 3], suggesting that alfentanil acts solely at central opioid receptors. Examining our results more closely (table 2), there may be a reduction in the incidence of pain in the alfentanil compared with the saline group from 24 s onwards, as there were four fewer patients with severe pain (four more with no pain) at both 24 and 32 s. However, if this was the result of a peripheral opioid effect, we would have expected to also detect a difference between groups at earlier times having already pretreated the forearm with alfentanil for 30 s.

There are no data to indicate the time for alfentanil to access a potential peripheral biophase. We accept that 30 s may be too short a time for alfentanil to achieve this. However, if a peripheral opioid action contributed to the analgesia observed by Fletcher, Seavell and Bowen at 30 s, we anticipated reproducing the effect by confining alfentanil to the arm for this time before injection of propofol. Increasing tourniquet time results in greater discomfort in the patient's arm and ethical considerations limited us to this time period for our initial study. However, the rapid onset time of alfentanil found by Fletcher, Seavell and Bowen is inconsistent with known pharmacodynamic data, as stated above. One explanation could be that when given as a rapid bolus the half-time for access to the central biophase is actually less than 54 s, and with a relatively mild pain stimulus, lower concentrations of alfentanil are required at receptors to provide adequate analgesia. It is also possible that we have used an inappropriate opioid and further studies might examine the use of more potent or lipid soluble opioids.

Psychophysical and electrophysiological responses to experimental pain may be influenced by sedation: comparison of the effects of a hypnotic (propofol) and an analgesic (alfentanil)

S. PETERSEN-FELIX, L. ARENDT-NIELSEN, P. BAK, M. FISCHER AND A. M. ZBINDEN

Summary

Sedation may influence the responses of some experimental pain models used to test analgesic efficacy. In this study we compared the effects of a sedative (propofol) and analgesic (alfentanil) on: nociceptive reflex to single and repeated electrical stimulations; mechanical pressure pain; and evoked potentials elicited by nociceptive (electrical and laser) and non-nociceptive (acoustical) stimulation. We studied 12 healthy volunteers with two subanaesthetic concentrations of propofol and two analgesic concentrations of alfentanil. Both propofol and alfentanil increased the threshold for nociceptive reflex to single electrical stimulations, but only alfentanil increased the threshold for nociceptive reflex to repeated electrical stimulations. The pressure pain tolerance thresholds were increased significantly by alfentanil, whereas propofol significantly decreased the thresholds (hyperalgesia). Propofol and alfentanil induced similar reductions in the amplitudes of the evoked potentials elicited by nociceptive (electrical and laser) and non-nociceptive (acoustical) stimulation, whereas only alfentanil reduced the perceived pain to nociceptive stimulations. We have shown that sedation can influence both the psychophysical and electrophysiological responses of some experimental pain tests used to measure analgesic efficacy, and that propofol in subhypnotic doses, has no analgesic effect on painful electrical and heat stimulations, but has a hyperalgesic effect on mechanical pressure pain. (*Br. J. Anaesth.* 1996; **77**: 165–171)

Key words

Anaesthetics i.v., propofol. Analgesics opioid, alfentanil. Pain, experimental.

Testing the sensory aspects of pain is hampered by the subjective and multidimensional nature of pain. This has led to a search for quantitative measures. The nociceptive withdrawal reflex to single electrical stimulations of the sural nerve has been proposed as a technique to assess the excitability of the nociceptive system [1, 2]. The size of the evoked potential elicited by painful stimuli has also been found to correlate with the state of the nociceptive system [3, 4]. For conditions when the subject cannot collaborate, nociceptive reflex and evoked potentials would appear to be adequate tests. Spinal polysynaptic nociceptive reflexes have been used in animals for decades. In a recent study [5], we found that subanaesthetic (0.10–0.26 vol% end-tidal) isoflurane concentrations increased significantly the threshold for nociceptive reflex to single electrical stimulations of the sural nerve, but did not change the reaction to pain elicited by heat, cold or pressure, or the threshold for nociceptive reflex to repetitive stimuli. This indicates that the increase in the threshold of the nociceptive reflex to single electrical stimuli might not reflect analgesia but could be caused by sedation. Furthermore, in another study [6] using similar subanaesthetic isoflurane concentrations, we found that the amplitude of evoked vertex potentials elicited by nociceptive laser and intracutaneous electrical stimulations decreased with increasing isoflurane concentration. But isoflurane caused a similar decrease in amplitudes of evoked vertex potentials elicited by non-nociceptive auditory stimuli, indicating that the decrease in amplitude was not caused by an analgesic effect of isoflurane, but could be a result of general depression of neuronal transmission.

Therefore, it seems possible that sedation could influence the responses of some experimental pain models used to assess analgesic efficacy. In this study we compared the effects of sedation (propofol) and analgesia (alfentanil) on the thresholds of the nociceptive reflex to single and repeated electrical stimulations, the amplitude of evoked vertex potentials elicited by nociceptive and non-nociceptive stimuli and detection and tolerance thresholds to mechanically induced pain.

Several studies [7–12] have been designed to see if hypnotics are hyperalgesic in subhypnotic doses, but results are conflicting. As propofol is one of the most widely used hypnotics in anaesthesia, and is also

used for sedation in intensive care, it is important to clarify further its influence on nociception in humans.

Subjects and methods

We studied 12 healthy volunteers (eight male), mean age 26 (range 20–42) yr. They were not receiving any medication, had no allergies or earlier adverse reactions to anaesthesia, and for the female volunteers, were not pregnant. Written informed consent according to the Helsinki Declaration was obtained, and the study was approved by the Ethics Committee of the Faculty of Medicine, University of Bern.

To minimize the risk of acid aspiration, volunteers were tested after a fasting period of at least 6 h. During testing volunteers rested comfortably in the supine position. An i.v. infusion of NaCl-glucose was started and haemoglobin oxygen saturation by pulse oximetry, ECG and non-invasive arterial pressure were monitored continuously during the study.

NOCICEPTIVE REFLEX THRESHOLD TO SINGLE STIMULI

The sural nerve was stimulated behind the lateral malleolus via surface electrodes filled with electrode gel (inter-electrode distance approximately 2 cm). A 25-ms, train-of-five, 1-ms, square-wave impulse (perceived as a single stimulus) was delivered from a computer-controlled constant current stimulator (University of Aalborg, Denmark). Electromyographic reflex responses were recorded from the middle of the biceps femoris and the rectus femoris muscles (surface silver–silver chloride electrodes). The EMG signal was amplified and filtered (1.5–150 Hz) by a Hellige (PPG Hellige GmbH, Germany) single channel EMG–EEG amplifier, recorded and analysed with NFRsys software (University of Aalborg, Denmark). The stimulation current was increased from 1 mA in steps of 1–2 mA until an ipsilateral reflex with an amplitude exceeding 20 μV for at least 10 ms was detected by the computer program. If a reflex was recorded three times at the same current intensity, this intensity was defined as the nociceptive reflex threshold to single stimulation. Maximal stimulation intensity was 80 mA. Eight reflexes, elicited with a stimulation intensity of 1.4 times the threshold intensity, were recorded, averaged and the root mean square (RMS) value in the 80–180-ms interval after the stimulus was calculated with EPsys software (University of Aalborg, Denmark). The volunteer then rated the perceived pain of the eight stimulations on a 10-cm visual analogue scale (VAS).

NOCICEPTIVE REFLEX THRESHOLD TO REPEATED STIMULI

The sural nerve was stimulated as described above, but the single stimulus was repeated five times with a frequency of 2 Hz, as described by Arendt-Nielsen and colleagues [13, 14]. Current intensity was increased from 1 mA in steps of 1–2 mA until a psychophysical or electrophysiological summation was detected by the computer program. The summation thresholds were defined as an increase in pain during the five stimulations (psychophysical summation threshold) or an increase in amplitude of the last one or two reflexes above a fixed limit of 20 μV for at least 10 ms (electrophysiological summation threshold). Maximal stimulation intensity was 80 mA.

MECHANICAL PRESSURE PAIN DETECTION AND PAIN TOLERANCE THRESHOLDS

Pressure pain detection and pain tolerance thresholds were measured on the centre of the pulp of the second (pain detection) and third (pain tolerance) finger of the right hand with an electronic pressure algometer (Somedic AB, Stockholm, Sweden) [15–17]. A probe with a surface area of 0.28 cm^2 was used, and the pressure increase was 30 kPa s^{-1}. Pain detection was defined as the point when pressure turned into pain, and pain tolerance as the point when the volunteer did not want the pressure to be increased further. For determination of both thresholds, the mean of two consecutive measurements was used.

REACTION TIME

A 1000-Hz tone was delivered from a computer with randomized intervals of 3–8 s, and a timer was started simultaneously. The volunteer was told to press a button as fast as possible after each tone. Reaction time was defined as the time from the tone until the volunteer pressed the button. The mean of three consecutive measurements was used.

EVOKED POTENTIALS

Argon laser stimulation

A 200-ms stimulus and a 3-mm laser beam diameter were used. Laser stimuli were applied to the dorsum of the hand (C7 dermatome). Repeated stimulation in the same area was avoided. The pain threshold was defined as a distinct sharp pinprick, and was calculated as the mean of five ascending and five descending series of stimulations. A laser stimulus of 1.4 times the initial pain threshold was used as stimulation for recording of the evoked potentials.

Electrical stimulation

An intracutaneous electrode, as described by Bromm and Meier [4], was used. The finger pulp of the third or fourth finger was stimulated with a blunt 1-mm steel pin electrode, with a digital ring finger electrode placed proximal as reference. A 25-ms, train-of-five, 1-ms, square-wave impulse (perceived as a single stimulus) delivered from a Digitimer DS7 constant current stimulator (Digitimer Ltd, UK) triggered by a Phillips PM5150 Generator (Phillips GmbH, Germany) was used as stimulus. The horn layer of the epidermis was scraped carefully in a 2 × 2-mm area. Intracutaneous placement was accepted when a stimulation current of less than 0.5 mA was felt as a distinct pinprick. The current was increased from 0 in steps of 0.2 mA until the volunteer scored the stimulus (VAS) as painful as the laser stimulus of 1.4 times the initial laser pain threshold. This intensity was used for recording of the electrical evoked potentials.

Auditory stimulation

Auditory evoked potentials were elicited by click stimulation (Medelec ST 10, Medelec Ltd, UK) with 90 dB applied binaural through acoustically shielded headphones.

Recording

The evoked vertex potentials were recorded from a needle electrode (scalp electrode, 0.3 × 10 mm, Dantec, Denmark), inserted at Cz′ *vs* a surface silver–silver chloride electrode on the right mastoid. The signal, in the interval of 0.5 s before the stimulus until 2 s after the stimulus, was amplified and filtered (0.1–30 Hz) with a Hellige (Hellige AG, Germany) single-channel EEG amplifier and recorded, averaged and analysed with EPsys software (University of Aalborg, Denmark). Evoked potentials from 16 stimulations were averaged.

Perceived pain from laser and electrical stimulations

After each series of 16 laser or electrical stimulations, volunteers rated perceived pain on a 10 cm VAS.

MEDICATION

Volunteers were tested on two different days, at least 1 week apart. They received, in randomized order, alfentanil on one day and propofol on the other. The medication was prepared by an anaesthetist who monitored the volunteer and study but did not take part in the measurements. The volunteer and other investigators were blinded as to the medication.

The first concentration of alfentanil (low dose) was attained by a loading dose of 7.5 $\mu g\ kg^{-1}$ i.v. followed by an infusion of 0.1 $\mu g\ kg^{-1}\ min^{-1}$ and the second (high dose) by a loading dose of 15 $\mu g\ kg^{-1}$ i.v. followed by an infusion of 0.3 $\mu g\ kg^{-1}\ min^{-1}$. The first propofol concentration (low dose) was attained by a loading dose of 0.5 $mg\ kg^{-1}$ i.v. followed by an infusion of 10 $\mu g\ kg^{-1}\ min^{-1}$ and the second (high dose) by a loading dose of 1 $mg\ kg^{-1}$ i.v. followed by an infusion of 30 $\mu g\ kg^{-1}\ min^{-1}$.

EXPERIMENTAL DESIGN

The tests were explained to the volunteer and a trial testing was performed in order to familiarize the volunteer with the procedure. Thereafter a baseline test series was performed. Further test series were performed 20 min after each loading dose during the infusion.

STATISTICAL ANALYSIS

The Friedman test for repeated measures analysis of variance on ranks, and the Student–Newman–Keuls test for multiple comparisons were used for statistical analysis. $P < 0.05$ was considered significant.

Results

NOCICEPTIVE REFLEX (TABLE 1)

The threshold for nociceptive reflex to single stimulations was increased significantly by propofol and alfentanil compared with baseline, but there was no difference in the increase caused by propofol or alfentanil. The RMS of the recorded reflex was decreased significantly by propofol and alfentanil compared with baseline, but the high dose of propofol decreased the RMS significantly more than the high dose of alfentanil. The perceived pain to stimulations with a current intensity of 1.4 times the baseline threshold intensity was not decreased by propofol, whereas alfentanil produced a significant decrease in pain intensity compared with baseline. Propofol did not change the psychophysical or electrophysiological threshold for summation of the nociceptive reflex, but both thresholds were increased significantly by alfentanil compared with baseline and the difference between high-dose propofol and high-dose alfentanil was significant.

MECHANICAL PRESSURE (TABLE 1)

The pressure pain detection thresholds tended to be decreased by propofol and increased by alfentanil, but differences from baseline were not significant. However, the difference between high-dose propofol and high-dose alfentanil was significant. The pressure pain tolerance thresholds were decreased significantly by propofol at the high dose, whereas alfentanil increased significantly the threshold at the high dose compared with baseline. The difference between high-dose propofol and high-dose alfentanil was significant.

REACTION TIME (TABLE 1)

Both propofol and alfentanil increased the reaction time compared with baseline, but a significantly larger increase was found with high-dose propofol compared with high-dose alfentanil.

EVOKED VERTEX POTENTIAL LATENCIES (TABLE 2)

A typical evoked vertex potential (laser) is shown in figure 1. Neither propofol nor alfentanil changed the latencies of the vertex evoked potentials, except for N1 latency at the high propofol concentration (increase of 10 % compared with baseline and 16 % compared with high-dose alfentanil).

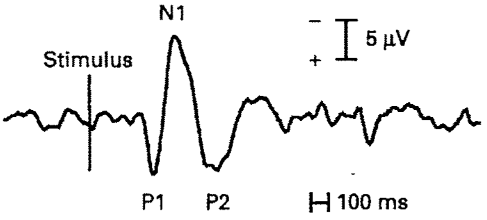

Figure 1 Laser evoked potential, which is the average of 16 evoked potentials elicited by short argon laser stimuli of 200 ms duration.

EVOKED VERTEX POTENTIAL AMPLITUDES (TABLE 3)

Neither propofol nor alfentanil changed the P1/N1 amplitudes of the laser evoked potentials. For the N1/P2 amplitudes of the laser evoked potentials and for the P1/N1 and N1/P2 amplitudes of the electrical and the auditory evoked potentials, both propofol and alfentanil reduced the amplitudes. In several cases (see table 3) propofol produced a significantly larger reduction than alfentanil. High-dose propofol and high-dose alfentanil induced the same amplitude reductions in the evoked potentials elicited by nociceptive stimuli (laser and electrical) as in the evoked potentials elicited by non-nociceptive stimuli (auditory) ($P = 0.12$ for P1/N1 amplitudes and $P = 0.21$ for N1/P2 amplitudes).

PERCEIVED PAIN TO LASER AND ELECTRICAL STIMULATIONS (TABLE 4)

Propofol did not reduce perceived pain (VAS scores) to laser and electrical stimulations, whereas high-dose alfentanil reduced significantly VAS scores

compared with baseline and low-dose alfentanil. VAS scores were also significantly smaller for high-dose alfentanil compared with high-dose propofol.

Discussion

We have shown that sedation can influence both the psychophysical and electrophysiological responses of some experimental pain tests used to measure analgesic efficacy. Propofol increased the threshold of the nociceptive reflex to single stimulations and decreased the amplitude of the evoked potentials elicited by nociceptive laser and electrical stimulations. This indicates that these may not, under all circumstances, assess the excitability of the nociceptive system. Propofol, in subhypnotic doses, had no analgesic effect on painful electrical and heat stimulations, but had a hyperalgesic effect on pressure pain.

NOCICEPTIVE REFLEX

Willer [18] investigated the relation between nociceptive reflex and perceived pain. The occurrence of the reflex was related closely to the pain threshold, and a linear relation was found between perceived pain and amplitude of the nociceptive reflex. This finding was confirmed later by Chan and Dallaire [19]. The reflex threshold to single stimuli has been found to increase with i.v. morphine [20], extradural morphine [21], i.m. alfentanil [22], but also with the weaker, non-opioid analgesics ketoprofen [23] and acetylsalicylic acid [24]. This indicates that the nociceptive reflex to single electrical stimulations of the sural nerve can be used to demonstrate analgesia produced by pure analgesic drugs. However, sub-anaesthetic (0.10–0.26 vol % end-tidal) isoflurane concentrations significantly increase the threshold for nociceptive reflex to single stimuli, but do not change the reaction to pain elicited by heat, cold or pressure, or the threshold of the nociceptive reflex to repetitive stimuli [5]. Training and attention has been shown to influence the pain threshold and the threshold for the nociceptive reflex [2], and distraction has been shown to decrease the nociceptive reflex [25]. In this study, propofol, in sedative doses, produced the same increase in the nociceptive reflex threshold to single stimulations as alfentanil, but showed hyperalgesic effects for tolerance to mechanical pressure. This indicates that the increase in threshold of the nociceptive reflex could be caused by sedation and not analgesia. The nociceptive reflex to single electrical stimulations may therefore not be a measure of analgesia when the drug tested also has sedative effects. As the nociceptive reflex has a sensory afferent and motor efferent component, the difference between propofol and alfentanil could be explained by stronger depression of the motor component by propofol. However, this would influence reflexes elicited by single and repeated stimulations in the same manner. Propofol did not change the threshold for temporal summation of the nociceptive reflex to repeated stimulations, indicating that the muscle component is not influenced significantly by propofol.

MECHANICAL PRESSURE

Early studies by Clutton-Brock [8, 26] and Dundee [9], using a relatively simple mechanical pressure pain model showed that small doses of thiopentone had a hyperalgesic effect. Our study showed that propofol, in subhypnotic doses, had a similar hyperalgesic effect on pressure pain. *In vitro* studies in single neurones [27] and isolated spinal cord models [10] showed that propofol and thiopentone depressed spinal nociceptive transmission, but they may have a different effect, through GABA inhibitory neurones, in the intact animal or human [28].

EVOKED VERTEX POTENTIALS

Arendt-Nielsen [3] correlated the amplitude or power of the long latency evoked vertex potential to an argon laser nociceptive thermal stimulation with the intensity of the perceived pain. With this method an analgesic effect of alfentanil [29], ibuprofen [30], paracetamol [31], codeine [32] and extradural morphine [33] has been demonstrated. A recent study failed to show an effect on laser evoked potentials of i.v. morphine [34]. In a recent review on nociceptive laser evoked vertex potentials by Arendt-Nielsen [35], it was suggested that sedation might influence the evoked potential. Evoked potentials to non-nociceptive stimuli should therefore be recorded as a control for sedation. We have shown recently that subanaesthetic isoflurane concentrations (0.10–0.26 vol% end-tidal) also decreased the amplitude of the evoked vertex potentials to painful laser and electrical stimuli [6]. But isoflurane produced a similar reduction in the amplitude of non-pain related auditory evoked vertex potentials recorded with the same paradigm, and did not reduce the perceived pain. In our study, propofol reduced the amplitude of evoked vertex potentials, but showed a hyperalgesic effect in the pain tolerance threshold to mechanical. This indicates that the reduction in amplitude of evoked vertex potentials by propofol and isoflurane is not caused by an analgesic effect. Anker-Møller and co-workers [7] also found a decrease in laser evoked vertex potentials with subhypnotic doses of thiopentone and propofol, but they did not measure the effect on non-pain-related potentials.

DRUG CONCENTRATIONS

The concentrations of propofol and alfentanil used in this study were chosen on empirical grounds, so that the low doses produced slight sedation (propofol) and slight analgesia (alfentanil), and the high doses distinct sedation and analgesia. The reaction time for low-dose propofol was slightly but not statistically increased compared with baseline, but for the high dose a significant increase was found compared with baseline and low-dose propofol. Low-dose alfentanil produced a slight but not significant increase in pain tolerance to mechanical pressure, but for the high dose of alfentanil a significant increase was found compared with baseline and the low dose. Furthermore, the threshold for the nociceptive reflex to single stimulations, and the decrease in the amplitude of the vertex potentials were not different for high-dose propofol and high-dose alfentanil. This indicates that the chosen doses were relevant according to the initial criteria, and that an effect of sedation on the nociceptive reflex and the amplitude of the vertex potentials could be investigated at these concentrations.

SHORT *VS* REPEATED OR LONGER LASTING STIMULATIONS

Arendt-Nielsen and co-workers [36, 37] and Brennum and co-workers [17, 38] have shown that brief localized nociceptive stimuli can be attenuated to a greater extent by extradural lignocaine or morphine than noxious stimulations of longer duration or involving larger areas. That central temporal and spatial summation of nociceptive stimuli are important for determination of anaesthetic efficacy is supported by our study. The responses to experimental pain tests involving short or single stimulations were influenced by the sedative effect of propofol, whereas tests involving longer lasting or repeated stimulations were not. Alfentanil showed the expected analgesia on both the short or single stimulations, and the longer lasting or repeated stimulations used in this study (these results are in accordance with previous studies [22, 29]).

PAIN DETECTION *VS* PAIN TOLERANCE THRESHOLDS

Measuring pain tolerance thresholds and not just pain detection was also important in this study. If we had only measured pain detection thresholds to mechanical pressure, we would not have detected the hyperalgesic effect of propofol on mechanical pain.

This study showed that when experimental pain models were used to measure an analgesic effect, the effects of sedation on both psychophysical and electrophysiological responses must be controlled. It is important to combine threshold measurements and electrophysiological responses with psychophysical pain ratings. Furthermore, models eliciting temporal or spatial summation, or both, of nociceptive stimuli appear to be less influenced by sedation.

Acknowledgement

The study was performed with support from the Desirée and Niels Yde Foundation, and the Danish Basic Research Foundation. The authors thank the anaesthesia research department for excellent technical assistance, especially D. Leibundgut.

Quantitative EEG in assessment of anaesthetic depth: comparative study of methodology†

C. E. THOMSEN AND P. F. PRIOR

Summary

Methodology for assessment of depth of anaesthesia based on analysis of the electroencephalogram (EEG) is controversial. Techniques range from display of single measures, for example median value of the frequency spectrum, to dedicated pattern recognition systems based on measures of several EEG features. We have compared the performance of four techniques using tape-recorded data from 23 patients anaesthetized with either halothane or isoflurane using standardized regimens. The techniques were: (1) median frequency, (2) spectral edge frequency, (3) the cerebral function analysing monitor (CFAM1) and (4) a depth of anaesthesia monitor based on EEG pattern recognition (ADAM). Dose–response curves are presented for stepwise increases in stable end-tidal concentrations of each agent. Results indicated considerable inter-patient variability and the limitations of single EEG measures, particularly with deeper anaesthesia producing a burst suppression pattern in the EEG. Pattern recognition techniques reduced these difficulties and appeared to be promising over a wide range of anaesthetic levels. (*Br. J. Anaesth.* 1966; **77**: 172–178)

Key words

Monitoring, electroencephalography. Anaesthesia, depth. Memory. Anaesthetics volatile, isoflurane. Anaesthetics volatile, halothane.

A simple objective method for assessment of depth of anaesthesia would be a useful facility in anaesthetic practice. The magnitude of the clinical problem of "awareness" during anaesthesia is now thought to be of the order of 1:1000 [1, 2]. The most appropriate means of recognizing it remains more controversial [2, 3].

The electroencephalogram (EEG) provides a direct measure of the functional state of the brain, permitting warning of the risk of awareness and detection of unnecessarily deep anaesthesia [4]. Blood or end-tidal concentrations of anaesthetic have been known for many years to show close correlations with EEG variables over the middle ranges of anaesthetic depth, leading to early attempts at automatic control [5]. In addition to questions of practicality, the use of EEG monitoring of anaesthesia remains debatable for three reasons: (i) EEG changes during anaesthesia tend to be agent-specific, (ii) the underlying principles of appropriate methods for monitoring have received only limited attention [6–10], (iii) the different techniques have rarely been subjected to rigorous comparative investigation [11, 12]. In this study we have compared the performance of four techniques of EEG monitoring for analysis of data tape-recorded from 23 patients anaesthetized with halothane or isoflurane. These are: median frequency (MF) [13, 14], spectral edge frequency (SEF) [15], the cerebral function analysing monitor (CFAM1) [8, 16] and the advanced depth of anaesthesia monitor (ADAM) [17–19]. The first two methods monitor single EEG features, while the latter two are essentially pattern recognition systems assessing multiple features.

Patients and methods

We were able to use EEG data recorded previously from 23 (ASA I) normotensive patients undergoing elective orthopaedic or gynaecological surgery from the study of Lloyd-Thomas, Cole and Prior [20] during closely controlled, stable, stepwise increases in end-tidal concentrations of either halothane or isoflurane.

The raw EEG data from left and right parietal regions were recorded originally on analogue tape simultaneously with the processing by the CFAM1 monitor [20]. The tapes have now been re-analysed using the ADAM system and comparisons with the original CFAM1 analysis are presented.

After Ethics Committee approval for the original study [20], premedication comprised papaveretum 0.2 mg kg^{-1} and hyoscine 4 μg kg^{-1} i.m., 90 min before anaesthesia. This was followed by induction with thiopentone 5 mg kg^{-1} and fentanyl 5 μg kg^{-1}. Tracheal intubation was performed after tubocurarine 0.5 mg kg^{-1}. Anaesthesia was maintained with either isoflurane or halothane and 66 % nitrous

oxide in oxygen. End-tidal carbon dioxide was maintained at 5%. If systolic arterial pressure decreased to less than 100 mm Hg, anaesthesia was lightened, and data from that part of the recording rejected from analysis, to avoid any possibility of unwanted effects of hypotension.

Twelve patients received isoflurane at end-tidal concentrations of 0.5, 1.0, 1.5 and 2.0 vol% and 11 patients received halothane at end-tidal concentrations of 0.5, 1.0 and 1.5 vol%. Artefact-free samples of 5 min duration were obtained during the control period with nitrous oxide in oxygen after a stabilization period of 15–20 min at each end-tidal concentration of the volatile agent and during recovery.

SIGNAL PROCESSING

The paper traces of the original unprocessed EEG were used to select artefact-free samples corresponding precisely to the marked periods analysed in the original study [20]. These were studied with the following methods of analysis.

Median and spectral edge frequencies

Median (MF) and spectral edge (SEF) frequencies were calculated as the 50th and 95th centiles of the accumulated value of the EEG power spectrum using the integrated frequency analysis in the ADAM system (fig. 1) based on 10th order autoregressive modelling.

Cerebral function analysing monitor (CFAM1)

After passage through an asymmetric band-pass filter, EEG amplitude and frequency were analysed digitally. The results were stored as numerical data and plotted on a screen and on paper. The clinician interpreted the charted results of analysis against an unprocessed EEG display when required. Amplitude and its variations were displayed as the mean, 90th and 10th centiles and maxima and minima outside these values. Frequency analysis using a modified zero-crossing technique, indicated every 2 s the percentage of the total energy falling into the following bands: beta2 (> 20 Hz), beta1 (14.3–20 Hz), alpha2 (10–14.3 Hz), alpha1 (7.7–10 Hz), theta2 (5.3–7.7 Hz), theta1 (3.5–5.3 Hz), delta2 (2.0–3.5 Hz), delta1 (1–2 Hz) and very low frequency ($<$ 1 Hz), together with separate detection of percent time with EEG suppression ($< 3\ \mu$V RMS).

For this study the results of CFAM1 digital analysis of 2-s segments of the EEG were obtained from the previous work on the same tape-recorded data [20]. In addition, a "fast/slow EEG frequency ratio" was calculated: (beta2 + beta1 + alpha2 + alpha1)/(theta2 + theta1 + delta2 + delta1).

Advanced depth of anaesthesia monitor (ADAM)

This system was based on a pattern recognition system which uses calculations of probabilities derived from previously studied normal reference distributions of EEG from patients receiving isoflurane and halothane at different concentrations [17–19]. Contiguous 2-s periods of the EEG were passed through a filter which first, limited low-frequency components likely to be artefactual and second, counteracted the inherent skewed frequency/amplitude distribution of the EEG. The features extracted from each sample represented both spectral distribution and amplitude of the EEG. The system was trained by a pattern processing technique (unsupervised repetitive hierarchical cluster analysis) to produce a set of reference patterns for halothane and isoflurane [17–19]. Within each set the individual patterns were grouped and assigned colours to represent specific depths of anaesthesia so providing a simple "anaesthetic scale" divided into six levels: "drowsy" (dark blue), "very light" (light blue), "light" (green), "normal surgical" (yellow), "deep" (purple) and "very deep" (red) anaesthesia. Awake states, artefacts and movements were assigned to the "background colour" of the display. This colour coding bypassed the problem of interpreting agent-specific data, in that the same overall scale was displayed for the equivalent ranges even though the EEG patterns from which it was derived were different for each agent.

Both the class probability histograms (distribution of recognized reference EEG patterns) and the simultaneous colour-coded density spectral arrays (EEG frequency distribution) were plotted with a time resolution of 10 s, each point displayed on the chart being based on a weighted average over the immediately preceding period (approximately 30 s). EEG suppression was detected separately using a method based on time domain descriptors over 0.25-s periods. This enabled us to modify the original pattern recognition so that 2-s periods with suppressions of 0.25–0.75 s were assigned to "normal anaesthesia", those with suppression of 0.75–1.25 s to "deep anaesthesia" and those with suppression of 1.25–2.00 s to "very deep anaesthesia". To facilitate comparison with other monitoring techniques, the class probability histograms were converted to a single numerical value representing the depth of anaesthesia such that the value 6.0 represented "very deep" anaesthesia and 1.0 represented "drowsy". A value for anaesthetic depth was then calculated for each 10 s.

STATISTICAL ANALYSIS

An unpaired two-tailed *t* test was performed on the group data for each step in end-tidal concentration of each anaesthetic, that is control period nitrous oxide in oxygen *vs* +0.5% end-tidal concentration of inhaled anaesthetic, +0.5% *vs* +1.0%, etc. and +1.5% or +2.0% *vs* "recovery".

All group data are presented as dose–response curves of the digital values from the various monitor outputs and derived variables against the end-tidal concentrations of the volatile agents, and data are displayed as mean (SD). The significance of the change in mean value compared with the previous state is given above the second of each pair using the following notation: *$P < 0.01$, **$P < 0.001$, ***$P < 0.0001$; symbols in parentheses indicate significant

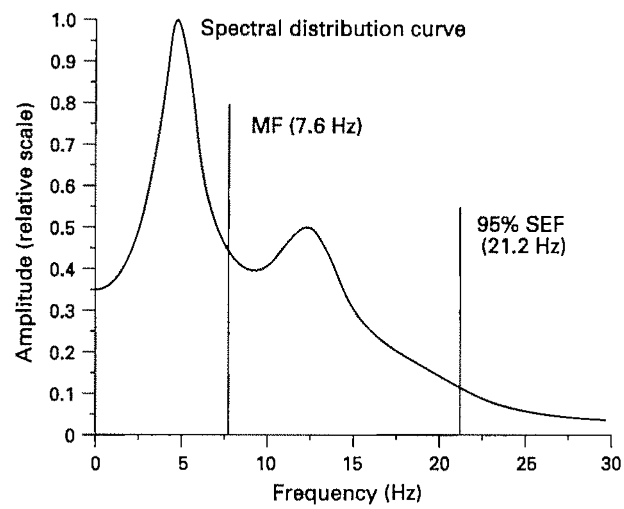

Figure 1 An example of power spectral analysis of an EEG segment during isoflurane anaesthesia. The spectral distribution was calculated using an autoregressive model of the 10th order. Each of the traditional single EEG measures, median frequency (MF) and spectral edge frequency (SEF), was derived from this curve, being the 50th and 95th centiles of the accumulated power value of the EEG frequency spectrum.

changes in the opposite direction to the overall trend for each variable (e.g. increased MF/SEF for increased anaesthetic depth).

Results

ISOFLURANE

The group data for MF (fig. 2) showed considerable inter-patient variability but this was less evident with increasing depth of anaesthesia up to an end-tidal concentration of 1.5%. From 1.5% to 2.0% there was no further change in MF. In contrast, the corresponding curve for SEF (fig. 3) did not exhibit a clear trend and inter-patient variability was high. Significant changes (decrease in SEF) were seen only from pure nitrous oxide in oxygen to +0.5% and from there to +1% end-tidal isoflurane concentration. With higher concentrations (+1.5%) SEF began to increase but thereafter (+2.0%) no further change occurred.

The CFAM1 amplitude data (fig. 4) replicated Bickford's 1950 work [5] showing an initial increase with light levels of anaesthesia and then a progressive decrease with increased depth of anaesthesia until burst suppression occurred. There was considerable variability in the CFAM1 group data and the only single frequency measures showing a continuous (but not significant for each step at $P < 0.01$) trend with increased depth of anaesthesia were theta1 and beta1. The calculated fast/slow ratio (fig. 5) based on the group data from the CFAM1 showed a clear trend up to +1.0% end-tidal concentration. However, a further increase produced only a small decrease in the fast-slow ratio. None the less, seen as group data this ratio did not, in contrast with other single EEG measures, reverse at +2.0% when two-thirds of patients developed burst suppression. Inter-patient variability was considerable, although it can only be indicated by the "standard deviation" bars shown in figure 5. Note that the standard

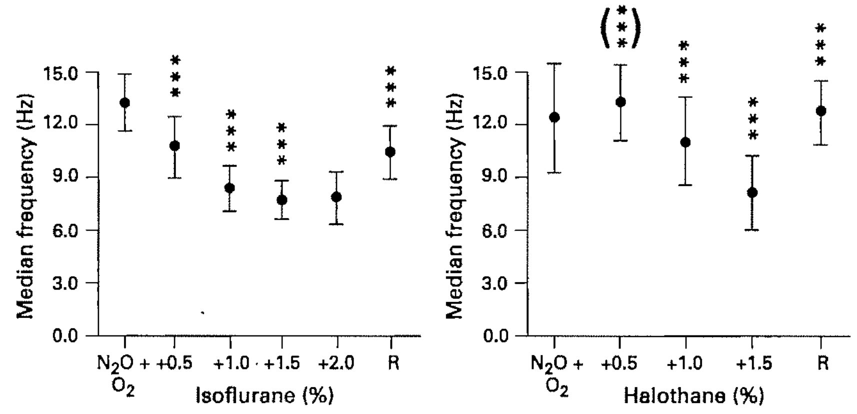

Figure 2 Median frequency; group data showing dose–response curves for patients receiving isoflurane ($n = 12$, left) and halothane ($n = 11$, right). The graphs show mean (SD) values during the sequence: nitrous oxide in oxygen ($N_2O + O_2$), step-wise increases in end-tidal concentration of the volatile agent and during recovery (R). The significance of changes in mean values (based on unpaired two-tailed t tests) compared with the previous state is given above the second of each pair using the following notation: *$P < 0.01$; **$P < 0.001$; ***$P < 0.0001$; symbols in parentheses indicate significant changes in the opposite direction to the overall trend for each variable (e.g. increased MF for increased anaesthetic depth).

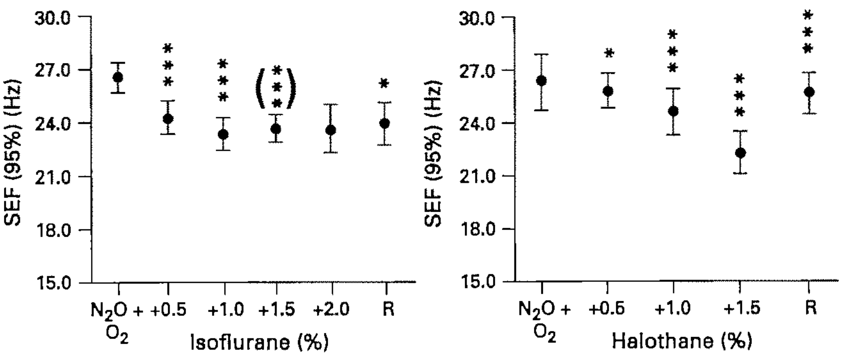

Figure 3 Spectral edge frequency (SEF); group data showing dose–response curves for patients receiving isoflurane ($n = 12$, left) and halothane ($n = 11$, right). Layout and symbols as in figure 2.

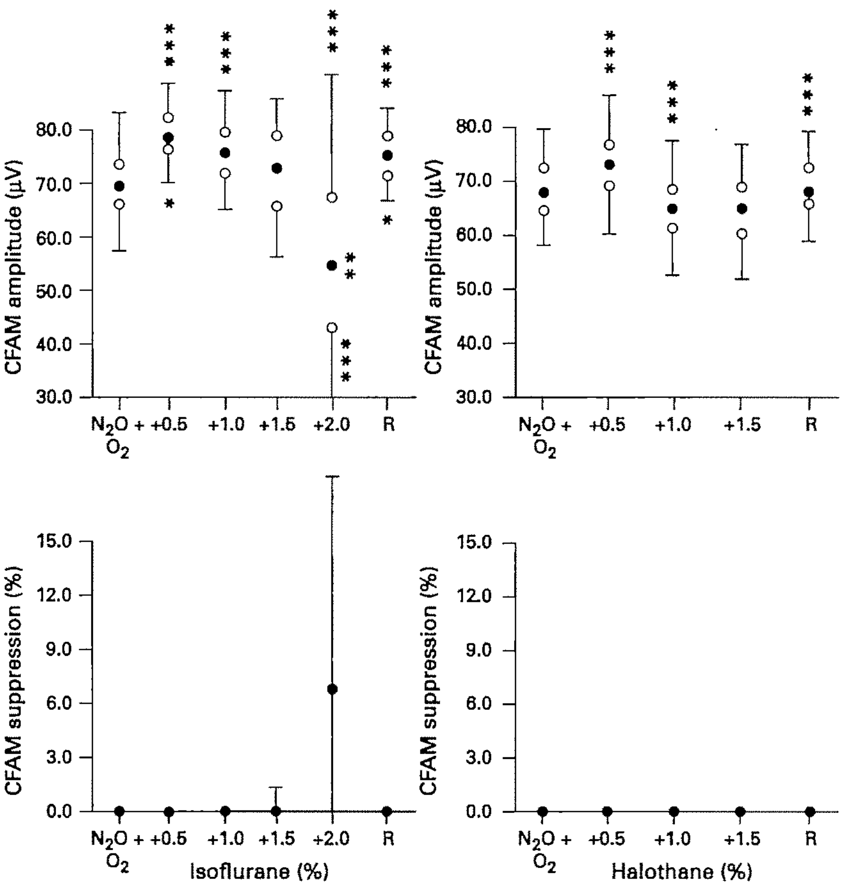

Figure 4 CFAM amplitude (top) and suppression (bottom); group data showing dose–response curves for patients receiving isoflurane ($n = 12$, left) and halothane ($n = 11$, right). Layout and symbols as in figure 2. CFAM1 amplitude values (peak-to-peak) are mean (●) and 90th and 10th centiles (○).

deviations are not legitimate for these CFAM1 group data as the frequency measures are based on pooled individual data and thereby not independent observations, and therefore no significance values could be calculated.

With the ADAM system (fig. 6), the group data showed highly significant and consistent trends with increasing end-tidal isoflurane concentrations, even though inter-patient variability was marked.

With most individual patients there was a clear initial decrease in MF towards deeper levels of anaesthesia with a relative low intra-patient variability. However, with increasing end-tidal concentrations of isoflurane from 1.5 to 2.0 %, MF showed a non-linear relationship in almost 50 % of patients, paradoxically suggesting "lightening" anaesthesia. Such patients all exhibited burst suppression patterns in the unprocessed EEG at an end-tidal isoflurane concentration of 2.0 % or, in some, even at 1.5 %. The corresponding SEF curves showed a poor correlation with increase in the end-tidal concentration. The spurious appearance of lightening of anaesthesia again occurred with burst suppression. Few of the individual curves produced a clear trend and inter-patient variability was high compared with the relatively small overall changes in SEF. Intra-patient variability was low, as with MF, but with small overall changes between different

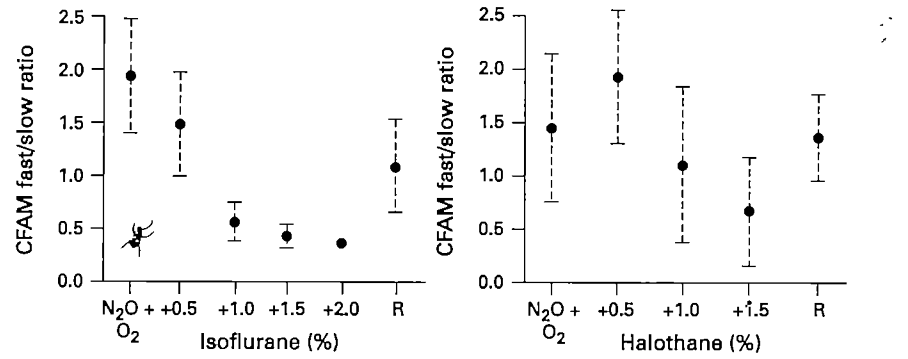

Figure 5 CFAM1 calculated fast/slow ratio; group data showing dose–response curves for patients receiving isoflurane ($n = 12$, left) and halothane ($n = 11$, right). Layout and symbols as in figure 2. The fast/slow EEG frequency ratio was calculated as (beta2 + beta1 + alpha2 + alpha1)/(theta2 + theta1 + delta2 + delta1). Note that SD, although indicated with dotted lines as a general guide, are not legitimate calculations as the frequency measures from the CFAM1 were based on pooled individual data and therefore not independent observations; thus no significance values could be calculated.

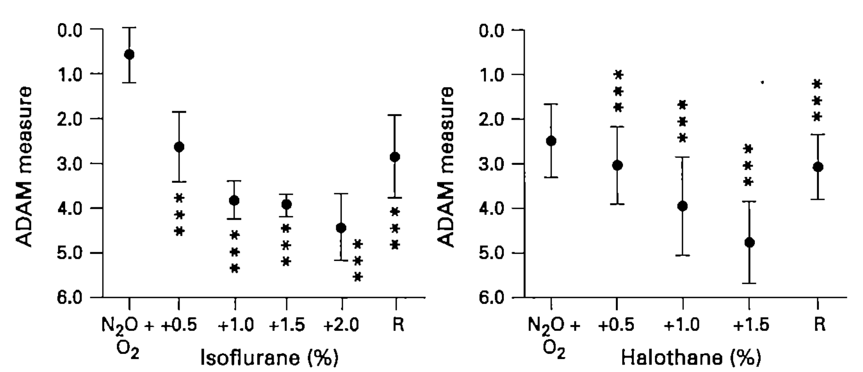

Figure 6 Anaesthetic depth, as indicated by the EEG pattern recognition system ADAM; group data showing dose–response curves for patients receiving isoflurane ($n = 12$, left) and halothane ($n = 11$, right). Layout and symbols as in figure 2. The scale on the vertical axis is based on a conversion of the class probability histograms to a single numerical value such that 0 is equivalent to the awake state, 1 to drowsiness, 2 to "very light" anaesthesia, 3 to "light" anaesthesia, 4 to "normal" surgical anaesthesia, 5 to "deep" and 6 to "very deep" anaesthesia.

anaesthetic concentrations. The CFAM1 showed, in all except one patient, an initial increase in amplitude with light levels of anaesthesia and then a progressive decrease with increasing end-tidal concentrations until onset of burst suppression. However, four patients not exhibiting burst suppression did not produce any further decrease in CFAM1 amplitude for 1.5 and 2.0% end-tidal concentrations. Intra-patient variability for CFAM1 amplitude was relatively low except during burst suppression, however, there was a considerable spread in absolute amplitude values between patients, indicating difficulties in producing a reliable measure of anaesthetic depth based solely on this feature.

The CFAM1 frequency measures showed marked intra- and inter-patient differences and the only consistent results were seen for beta1 + 2 and theta1 bands. EEG activity in the entire beta frequency band seemed significantly suppressed for moderate to deep levels of anaesthesia, but inter-patient variability for light levels was quite high. In most patients the theta1 band showed a clear trend to increase with increasing end-tidal concentrations. The calculated fast/slow ratio based on the pooled individual data from the CFAM1 decreased with end-tidal isoflurane concentrations up to 1% but in the majority of patients a further increase in end-tidal concentration produced only minor changes. For three patients an initial increase was seen in the fast/slow ratio comparable with that in the CFAM1 amplitude measures. In four patients there was a small increase in the fast/slow ratio during burst suppression at 2.0% end-tidal isoflurane. ADAM, the pattern-recognition system, showed consistent and uniform dose–response curves to approximately 1.5% in all except three patients with relatively low intra- and inter-patient variability. In these three patients the dose–response curve flattened just before short suppressions first appeared in the raw EEG, indicating difficulties in detection of the first signs of discontinuity in the EEG.

HALOTHANE

The group data for MF (fig. 2) showed inconsistency in trend and high inter-patient variability, even though changes for each step increase in halothane concentration were significant. The corresponding values for SEF (fig. 3) decreased progressively with increased end-tidal concentrations, but the changes for the first step (nitrous oxide in oxygen to +0.5%) were significant only at $P < 0.01$. The CFAM1 amplitude measures (fig. 4) showed only a non-significant trend with increasing halothane concentration and no EEG suppressions were detected in any patient. All CFAM1 frequency measures showed considerable variability as in the isoflurane study. The only frequency variables indicating a consistent trend with increased depth of anaesthesia were beta1+2 and, to a limited degree, theta1. However, although beta1 changed significantly ($P < 0.01$) for the first two steps, individual traces were variable. The calculated CFAM1 fast/slow ratio (fig. 5) showed a trend similar to MF, but the variability in EEG frequency changes with halothane reduced the potential value of this ratio. In contrast, the ADAM system (fig. 6) gave a near-linear relation with end-tidal concentration of halothane for group data but tended to overestimate the depth of anaesthesia for pure nitrous oxide in oxygen because of inconsistent initial changes in three patients (see below).

In individual patients, neither MF nor SEF produced a consistent trend with increasing end-tidal halothane concentrations. In four of 11 patients there was a decrease in MF and SEF after the period of nitrous oxide in oxygen alone, but it should be noted that inter-patient variability was considerable. Of the individual CFAM1 measures, none showed any significant trend with increased end-tidal concentration except for beta1+2 which, for all but two patients, appeared markedly suppressed for end-tidal concentrations of +1.5% or above. The individual CFAM1 amplitude dose–response curves were very variable with no consistent trend. No uniform pattern was evident with any of the CFAM1 frequency variables except theta1 which, in five of the patients increased with increasing end-tidal concentration. After an initial variable increase, the fast/slow ratio decreased in all patients with end-tidal concentrations greater than +1.5%. With the ADAM system there were more consistent trends but inter-patient variability was marked, especially compared with the isoflurane study. For three of the 11 patients, the ADAM system wrongly assessed pure nitrous oxide in oxygen effects as representing deeper anaesthesia than during +0.5% end-tidal concentration of halothane. A similar problem occurred in six patients for MF and in four for SEF.

Discussion

We have compared the performance of four different techniques for assessment of depth of anaesthesia with the volatile agents isoflurane and halothane using the same set of tape-recorded data obtained in a previous study [20]. As in other studies it was evident that methods using a single EEG feature are inadequate over the range of anaesthetic depths which include EEG burst suppression pattern [6, 12].

The CFAM1 had the advantage of displaying multiple features so that the user could identify individual changes with alterations in end-tidal concentration and, importantly, immediately recognize the burst suppression pattern. In addition to indicating deep anaesthesia, this pattern may have serious implications (e.g. hypoxia or ischaemia). However, it requires experience to learn the overall CFAM pattern combinations for each anaesthetic and with the launch of each new agent, further patterns would have to be assimilated. These considerations appear to have been addressed in a new version (CFAM3) about which preliminary information has been made available [personal communication, D. E. Maynard, 1995]. The development of the ADAM system uses a different approach where an unsupervised clustering technique is used to define a reference set of naturally occurring EEG patterns for different types and depths of anaesthesia. These reference patterns are then used in on-line pattern recognition during anaesthesia to display a simple-to-interpret, anaesthetic depth indicator. As yet the data base is relatively small and limited to the anaesthetic techniques on which it has been trained. We are presently completing studies to extend the anaesthetic database and on detection of changes caused by other aspects or complications of surgery and anaesthesia (asymmetries of any variables, distinction between deep anaesthesia, hypothermia and hypoxic–ischaemic complications).

The two examples of single EEG feature methods which we have investigated, MF and SEF, failed to characterize deepening anaesthesia when the burst suppression pattern had appeared in the EEG. Typically this EEG pattern was seen when end-tidal isoflurane concentrations were in the range +1.5 to +2.0%. This problem of burst suppression pattern in the EEG has not been addressed adequately by previous authors who have recommended single feature methods (MF or SEF) on the basis of studies which, while providing elegant correlations within the range of relatively low concentrations of various agents, have not included depths of anaesthesia normally associated with EEG suppressions [13, 14, 21]. Indeed some possibility of misclassification still exists with the ADAM system during early burst suppression. It should be noted that the CFAM1, in spite of the above mentioned problems regarding the complexity of a multivariate display, does clearly indicate even very early burst suppression patterns.

The limitations of single EEG measures for monitoring depth of anaesthesia have been indicated by others [6, 12] but the approach of using a pattern recognition system based on multiple features has received only limited attention [17–19] and has not previously been subjected to comparative studies. On the evidence of the results we believe it would be fruitful to explore such systems further. The techniques appear to have the potential of overcoming many of the difficulties previously associated with EEG monitoring of depth of anaesthesia. Moreover, on theoretical and practical grounds they are likely to be more generally applicable than methods based on evoked potential monitoring. Evoked potentials provide a crucially important tool for assessment of integrity of neural pathways during some spinal and intracranial surgical procedures. However, they require a skilled operator and their value for assessing anaesthetic depth in an individual patient appears to apply mainly to the lighter levels of anaesthesia.

Only when a highly reliable measure of depth of anaesthesia can be obtained in an individual patient will we achieve the aim of clinical acceptability.

Spectral edge frequency of the electroencephalogram to monitor "depth" of anaesthesia with isoflurane or propofol

D. SCHWENDER, M. DAUNDERER, S. MULZER, S. KLASING, U. FINSTERER AND K. PETER

Summary

To determine threshold values, sensitivity and specificity of the spectral edge frequency (SEF) of the electroencephalogram (EEG) that indicate intraoperative movements, we studied 49 patients undergoing elective laparotomy. Extradural analgesia was used in all patients. To maintain general anaesthesia, patients in group 1 ($n = 23$) received 0.4–1.2 vol% isoflurane and patients in group 2 ($n = 24$) propofol 3–5 mg kg^{-1} h^{-1} i.v. During operation and emergence from anaesthesia, spontaneous purposeful movements were documented. The EEG was recorded continuously in the awake state until the end of anaesthesia. Power spectral analysis calculated the SEF and power in the delta, theta, alpha and beta bands and the delta ratio. Adequate anaesthesia caused a statistically significant decrease in SEF from 16 to 12 Hz. Power in the beta band decreased and power in the theta band and total power increased compared with the awake state. Before and during movements observed in the intraoperative period or during emergence from general anaesthesia, SEF increased from 12 to 18 Hz, the power in beta band increased and theta power decreased compared with the state of adequate anaesthesia. A threshold value of SEF 14 Hz to predict movements during anaesthesia had a sensitivity of 72% and specificity of 82%. (*Br. J. Anaesth.* 1996; **77**: 179–184)

Anaesthetics i.v., propofol. Anaesthetics volatile, isoflurane. Brain, electroencephalography. Monitoring, electroencephalography. Anaesthesia, depth. Memory.

Many general anaesthetics change the spontaneous activity of the electroencephalogram (EEG) from low voltage fast wave to high voltage slow wave patterns progressively with increasing serum or end-expiratory concentrations. Burst suppression patterns may occur at very high doses of some general anaesthetics [1]. With power spectral analysis of the EEG signal, single variables could be derived from the native EEG, such as spectral edge frequencies (SEF), for example SEF 95, SEF 90, SEF 50 = median frequency [2, 3]; the spectral edge frequency is the frequency below which 95%, 90% or 50%, respectively, of the total EEG power is located. SEF 95, 90 and median frequency (SEF 50) are reduced with increasing serum or end-tidal concentrations of many general anaesthetics or opioid analgesics [4–11]. Furthermore, it has been suggested that SEF may be used to measure depth of anaesthesia and indicate arousal during emergence from general anaesthesia [12–14]. Nevertheless, SEF has not been used to monitor depth of anaesthesia in routine clinical practice. In this study, we have determined threshold values, sensitivity and specificity of the SEF that indicate intraoperative movements during general anaesthesia with isoflurane or propofol.

Patients and methods

After obtained Institutional Ethics Committee approval and informed consent, we studied 47 patients, aged 21–79 yr, ASA grades I and II, undergoing elective gynaecological or urological laparotomy. After oral premedication with a benzodiazepine (clorazepate dipotassium 20 mg) 45–60 min before anaesthesia, continuous electrocardiograph electrodes (ECG) and an i.v. catheter were inserted, and a continuous extradural block was performed at L3–4 or L4–5. Using 0.5% bupivacaine, the anaesthetic level was maintained at T4–5. Patients were allocated randomly to one of two groups (group 1, $n = 23$; group 2, $n = 24$). I.v. general anaesthesia was induced in group 1 with thiopentone 5 mg kg^{-1} and in group 2 with propofol 2 mg kg^{-1}. After induction of general anaesthesia and loss of consciousness (no response to verbal commands, loss of eyelid reflex), the patient's lungs were ventilated with 100% oxygen via a face mask. Vecuronium 0.1 mg kg^{-1} was given for neuromuscular block, the trachea was intubated and the lungs ventilated with 50% nitrous oxide in oxygen. No other neuromuscular blockers were used. To maintain general anaesthesia, patients in group 1 received 0.4–1.2 vol% isoflurane and patients in group 2 propofol 3–5 mg kg^{-1} h^{-1} i.v. End-expiratory concentrations of isoflurane were monitored continuously with a multi-gas analyser (Capnomac Ultima, Datex Instrument Corporation, Helsinki, Finland). Heart rate (by a three-lead ECG), systemic arterial pressure (by an arterial cannula in the radial artery) and central venous pressure (by a central venous catheter in the internal jugular vein)

DIERK SCHWENDER*, MD, MICHAEL DAUNDERER, STEPHAN MULZER, SVEN KLASING, UDILO FINSTERER, MD, KLAUS PETER, MD, Institute for Anaesthesiology University of Munich, Germany. Accepted for publication: March 13, 1996.

were recorded continuously. Mean arterial pressure was maintained greater than 70 mm Hg. Body core temperature was measured by an oesophageal temperature probe and maintained greater than 35.5 °C using heated blankets and warmed infusions. Controlled ventilation was adjusted to maintain normocapnia (end-expiratory carbon dioxide concentration 4.8–5.3 kPa) and verified by intermittent arterial blood-gas analysis. Individual doses of anaesthetics were guided by clinical signs of adequate anaesthesia, that is changes in arterial pressure, heart rate, sweating and tear production. Light anaesthesia was indicated by the "pressure rate, sweating and tears" (PRST) score [15]. A PRST score greater than 2 or spontaneous movements of the patients was defined as indicative of light anaesthesia. Spontaneous purposeful movements of the head and limbs, eye-opening or other facial movements were documented. Whenever movements occurred, the dose of the anaesthetic was increased to induce a clinically adequate level of anaesthesia. To evaluate conscious recall of anaesthesia and surgery, the patients were asked after operation to remember explicitly anything perceived during anaesthesia.

To obtain two-channel recordings of the EEG, silver electrodes were placed at C3/C4 (positive) and mastoids on both sides A1/A2 (negative) against the forehead as common electrode (FPZ), according to the international 10-20 system. The impedance of all electrodes was maintained less than 3000 Ω. A Cerebotrac 2500 (SRD Medical Ltd, Shorashim, Israel) was used to record, analyse and store the EEG signal. Bandpass filters were set at 1.5–30 Hz and amplifier sensitivity was 200 μV. The automatic artefact rejection was active and line current frequency suppression was set at 50 Hz. On-line power spectral analysis was performed using fast Fourier transformation (FFT). Epoch length of EEG acquisition was 4 s. Power spectrum was displayed as density spectral array. Spectral edge frequency 90 (SEF 90 = the frequency below which 90% of the EEG power is located) was calculated. Spectral bands of 0–4 Hz (delta) 4–8 Hz (theta), 8–13 Hz (alpha) and 13–30 Hz (beta) were analysed and the power of the spectral bands were calculated and expressed as percentage of total power. The delta ratio (ratio of power in the 8–30 Hz band to power in the 0–4 Hz band) was calculated. For off-line analysis, data were stored on a notebook computer (Compaq Ltd 25, Compaq Computer GmbH, München, Germany). Values for each of the derived variables were determined by averaging the data from 30 consecutive epochs. Where the value for an individual epoch was more than 2 SD from the mean it was omitted and replaced by an additional epoch. The EEG was recorded continuously on-line awake and during induction and maintenance of general anaesthesia until the end of anaesthesia, when the patients were extubated and had recovered from anaesthesia.

Results are presented as mean (SD). Cardiovascular variables and spontaneous movements were correlated by a time series analysis. For SEF 90 and the power bands beta, alpha, theta, delta and the delta ratio, the Wilcoxon test was used. Sensitivity (number of correctly predicted movements/total number of movements), specificity (number of correctly predicted situations of adequate anaesthesia/total number of situations of adequate anaesthesia) were calculated. Statistical significance was assumed if $P < 0.05$ after Bonferroni's correction for multiple comparisons.

Results

The two groups were comparable in age, sex distribution, weight, height, ASA physical status, type and dose of premedication, type of surgery, total time of surgery and anaesthesia, and total dose of bupivacaine (table 1).

Systolic (SAP) and diastolic (DAP) arterial pressure and heart rate (HR) awake, during maintenance of anaesthesia and during emergence from anaesthesia are presented in table 2. There was no significant change in heart rate. SAP and DAP decreased slightly during maintenance of anaesthesia and returned to awake baseline values at the end of anaesthesia in both groups. Sixteen movements in group 1 and 20 movements in group 2 were observed during maintenance of anaesthesia. All patients in each group moved spontaneously during emergence from anaesthesia shortly before tracheal extubation. The trachea of all patients was extubated and the patient had regained consciousness during the study at the end of anaesthesia. There was no correlation between haemodynamic data and movements, in the intraoperative period or during emergence from anaesthesia. At the postoperative interview no patient had explicit recall of intraoperative events.

Figure 1 shows the typical course of the power spectrum displayed as density spectral array and the spectral edge frequency awake, during induction and maintenance of general anaesthesia with isoflurane (fig. 1A) and propofol (fig. 1B), and during emergence from anaesthesia. With induction of general anaesthesia and during adequate general anaesthesia (no movement), in both patients SEF decreased from the awake baseline value of 18–20 Hz to 12–14 Hz. When a movement occurred during anaesthesia, SEF increased to the awake baseline value of 18–20 Hz. Deepening of general anaesthesia caused a decrease in SEF of 12–14 Hz. During emergence from general anaesthesia, SEF increased and at the end of anaesthesia shortly before extubation it returned to the awake baseline value of 18–20 Hz.

Mean SEF (Hz), total power (μV^2) and relative power in the frequency bands, delta, theta, alpha, beta and the delta ratio ($\alpha + \beta/\delta$) of the isoflurane and propofol groups awake, during maintenance of adequate general anaesthesia (no movement), before and during intraoperative spontaneous movements and during emergence from general anaesthesia are shown in table 3. Changes in SEF and the power bands were similar in both groups. Adequate anaesthesia caused a statistically significant decrease in SEF. Before and during intraoperative spontaneous movements in both groups there was a statistically significant increase in SEF compared with the state of adequate anaesthesia. The same was

Table 4 Threshold values of EEG variables for movements during anaesthesia

	Threshold value	Sensitivity (%)	Specificity (%)
Group 1 (isoflurane)			
SEF (Hz)	14	73.33	76.26
Total power (μV)	100	95.00	17.09
δ band (%)	40	81.67	18.18
τ band (%)	20	53.33	73.23
α band (%)	30	15.00	57.87
β band (%)	30	21.67	95.98
Delta ratio	3.0	25.81	83.33
Group 2 (propofol)			
SEF (Hz)	14	70.67	88.24
Total power (μV)	100	82.67	30.33
δ band (%)	40	74.67	21.80
τ band (%)	20	72.00	61.24
α band (%)	30	25.68	59.72
β band (%)	30	28.00	98.58
Delta ratio	3.0	34.25	93.33
Groups 1+2			
SEF (Hz)	14	71.85	82.34
Total power (μV)	100	88.15	23.90
δ band (%)	40	77.78	20.05
τ band (%)	20	63.70	67.08
α band (%)	30	20.90	58.82
β band (%)	30	25.19	97.32
Delta ratio	3.0	30.37	88.48

increased during adequate anaesthesia and decreased during intraoperative movements and emergence from anaesthesia in both groups. Relative power in the delta and alpha bands and the delta ratio did not change significantly during anaesthesia.

In table 4 are shown threshold values for SEF and the relative power in the delta, theta, alpha and beta bands, with their calculated sensitivities and specificities within and between groups to separate adequate anaesthesia (no movement) from intraoperative spontaneous movements. SEF of 14 Hz provided a sensitivity of 73% and a specificity of 76% in the isoflurane group, and a sensitivity of 70% and a specificity of 88% in the propofol group. Between groups a threshold value of SEF 14 Hz had a sensitivity of 72% and a specificity of 82% to separate adequate anaesthesia (no movement) from intraoperative spontaneous movements.

Discussion

There was no correlation in our study between physiological signs of wakefulness (increase in heart rate and arterial pressure) and motor signs of wakefulness during a combination of extradural analgesia with bupivacaine and general anaesthesia with isoflurane or propofol. This observation may be explained by the extensive extradural block in all patients during surgery. It interfered with the cardiovascular variables by attenuating arterial pressure responses by sympathetic block. In this study we combined regional and general anaesthesia to minimize the effect of pain on the level of arousal. Furthermore, extensive spinal block was thought to inhibit reflex movements in response to pain, as intended by the spinal cord. This should facilitate the interpretation of patient movement, as intended by the cortex.

SEF decreased during general anaesthesia with isoflurane or propofol compared with the awake state. During intraoperative spontaneous movements and emergence from anaesthesia with isoflurane or propofol, SEF increased to near awake baseline values. Nevertheless, because of the range of overlap of SEF during adequate anaesthesia (no movement) and intraoperative spontaneous movements, sensitivity and specificity were only 70–88% within and between groups.

Schwilden, Schüttler and Stoeckel used the median frequency of the EEG in volunteers to define depth of anaesthesia and to develop pharmacokinetic–pharmacodynamic models during i.v. anaesthesia. They found, during a threefold repetitive infusion of etomidate in volunteers, a correlation between median frequency and serum concentrations of the i.v. anaesthetic [8]. With increasing serum concentrations of etomidate, median frequency decreased from the awake baseline value of about 9 Hz to the anaesthetic value of approximately 2 Hz. With decreasing blood concentrations of etomidate, median frequency increased and returned to the awake value of approximately 8 Hz. A similar relation between median frequency and blood concentrations of i.v. anaesthetics was observed by Schwilden, Schüttler and Stoeckel [9] and Schüttler and colleagues during anaesthesia with methohexitone, propofol and ketamine [11, 16]. The awake median frequency in their studies was approximately 9 Hz, loss of consciousness occurred at about 5 Hz, the corneal reflex was absent at approximately 2 Hz and a burst suppression pattern occurred at about 1.5 Hz. The burst suppression patterns disappeared at median frequencies of approximately 1.8 Hz, the corneal reflex returned at approximately 2 Hz, responsiveness returned at approximately 5 Hz and orientation occurred at approximately 6–7 Hz. In one study, concentrations of isoflurane and nitrous oxide of 1.3 and 1.5 MAC, respectively, were associated with an EEG median frequency of less than 5 Hz and adequate intraoperative anaesthesia

[10]. In this study median frequency was greater than 5 Hz, when subjects were conscious and responsive.

Drummond and co-workers studied the processed EEG during general anaesthesia with isoflurane and during emergence from anaesthesia [12]. Most patients showed an increase in median frequency and SEF immediately before arousal compared with anaesthesia. Nevertheless, because of the range of overlap between anaesthesia and arousal, the sensitivity and specificity of median frequency and SEF in predicting arousal during anaesthesia was low, as in this study. They concluded that none of the EEG descriptors can serve as a completely reliable predictor of imminent arousal during anaesthesia.

Dwyer and co-workers found that the EEG could not predict depth of isoflurane anaesthesia [17]. They found that EEG activity and SEF decreased dose-dependently during anaesthesia with isoflurane. Nevertheless, the SEF of patients who moved purposefully in response to incision was 19.8 and did not differ from the SEF of 19.3 in patients who did not move. Memory of information presented during general anaesthesia did not correlate with values of any of the derived EEG variables. Response to commands in the intraoperative period was associated with lower anaesthetic concentrations of isoflurane, but there was no difference in the derived EEG variables between responders with an SEF of 22.1 and non-responders with an SEF of 21.3.

Unfortunately, there are no other clinical studies that have investigated the usefulness of the derived EEG variables, median frequency or SEF, in predicting intraoperative movements, arousal, awareness or memory formation for the commonly used anaesthetics. It seems that the typical clinical environment, in which multiple drugs are given and clinical end-points are not defined clearly, the success in determining depth of anaesthesia and predicting intraoperative movements and arousal with EEG variables is limited.

The reinforced laryngeal mask airway for dento–alveolar surgery

A. C. QUINN, A. SAMAAN, E. M. MCATEER, E. MOSS AND M. VUCEVIC

Summary

We have evaluated the reinforced laryngeal mask airway (LMA) for use during dento–alveolar surgery in 100 ASA I and II day-case patients allocated randomly to receive either a nasotracheal tube or reinforced LMA. We recorded ease of airway insertion, airway complications, quality of recovery and replies to a 24-h postoperative questionnaire. In addition, a fibreoptic assessment was made of laryngotracheal soiling, and the effect of head movement and the position of the reinforced LMA. There were no significant differences in difficulty in airway positioning or perioperative oxygen desaturation. Nineteen patients in the nasotracheal tube group had epistaxis ($P = 0.001$) and laryngotracheal soiling occurred in three of these patients. Two reinforced LMA were dislodged on moving into the operating theatre and in a further five patients in this group there was partial airway obstruction (compared with none in the nasotracheal tube group; $P = 0.018$) which was caused by downward pressure on the mandible by the surgeon. There were no differences in postoperative complications. No surgeon reported poor access to the operating field. Overall the reinforced LMA provided satisfactory conditions for this surgery but vigilance of the airway was required, especially at the time of extraction. (*Br. J. Anaesth.* 1996; **77**: 185–188)

Key words

Equipment, masks anaesthesia. Complications, airway obstruction. Surgery, dental.

Anaesthesia for oral surgery requires a technique which provides a stable, unobstructed airway and permits good surgical access with few complications. Recent studies on adenotonsillectomy procedures [1, 2] showed that the Brain reinforced laryngeal mask airway (LMA) provided a satisfactory airway and protection against soiling from the operation site. The reinforced LMA has potential for airway management during surgical exodontic procedures and although this is a commonly used technique [3, 4], a recent review [5] has highlighted the lack of standardized, randomized studies in this area. To our knowledge no study has been performed to quantify the problems in a standardized, controlled manner.

In this study, we assessed the following: maintenance of the airway, protection against soiling and any effects resulting from manipulation of the temporo–mandibular joint, and movement of the reinforced LMA, which are more pronounced in oral surgery.

Patients and methods

After obtaining local Ethics Committee approval and written, informed consent, we studied 100 consecutive ASA I and II patients undergoing day-case oral surgery (predominantly surgical extraction of wisdom teeth). Patients were allocated randomly to one of two groups: group A received the reinforced LMA and group B the plastic nasotracheal Mallinckrodt tube (size 7.0 in men and 6.5 in women). Patients were aged 18–60 yr with no pre-existing lung pathology. Exclusion criteria were contraindications to the use of the reinforced LMA, such as obesity and gastro–oesophageal reflux.

The reinforced LMA was inserted according to the manufacturer's recommended technique [3]. Most adults had a size 4, apart from females < 50 kg. In both groups anaesthesia was induced with propofol 1–2 mg kg^{-1} and fentanyl 1 µg kg^{-1}, and maintained with isoflurane and 70 % nitrous oxide in oxygen. In group A, patients breathed isoflurane and nitrous oxide in oxygen spontaneously via the reinforced LMA. In order to facilitate moving the tube to the other side of the mouth if bilateral procedures were being undertaken, the reinforced LMA was not taped in position. In group B, mivacurium 0.15 mg kg^{-1} was used to facilitate nasotracheal intubation and maintain paralysis for IPPV with isoflurane and nitrous oxide in oxygen. The nasopharynx was not treated with a vasoconstrictor before inserting the nasotracheal tube, however, the nasotracheal tubes were warmed before use. During the procedure all patients received ketorolac 10 and 20 mg i.v. for postoperative analgesia and a gauze pharyngeal pack was inserted in both groups.

The following were monitored throughout the procedure: ECG, non-invasive arterial pressure, oxygen saturation, inspired oxygen and end-tidal carbon dioxide concentration, and isoflurane concentrations. Airway pressure and neuromuscular function were monitored in patients in group B. The technical problems encountered with each airway were noted. These included difficult insertion, epistaxis, displacement of the reinforced LMA,

repositioning and whether or not mandibular support was required to maintain airway patency at any point in the procedure.

After surgery we increased the inspired concentration of isoflurane to 3% in 100% oxygen, the larynx, trachea, or both, were inspected for soiling from blood or secretions, and the position of the reinforced LMA was checked. We used the Keymed fibreoptic laryngoscope and advanced it no further than just through the grill of the mask or past the tip of the nasotracheal tubes unless there was obvious airway soiling distally. In group A patients undergoing bilateral procedures, the airway was also examined after extractions on the first side in order to assess any effect of the surgeons moving to the contralateral side. At the end of surgery the pharyngeal pack was removed, the pharynx was cleared by suction and the patients emerged from anaesthesia and in the left lateral position, head down. In group A, the reinforced LMA was removed in recovery when the patients awoke; the dental packs on the extracted tooth sockets prevented biting on the mask. In group B patients, the trachea was extubated with the patient awake.

During recovery, the following variables were noted by the recovery staff: airway maintenance—easy, mandibular support or airway required, airway conditions—good, coughing, biting, laryngeal spasm, suction—easy/difficult/not required, and desaturation < 95%. After the procedure the anaesthetist and surgeon were asked to grade the quality of the airway and surgical access, respectively, as excellent, good, fair or poor.

Before the patients left the institute they were given a questionnaire to complete 24 h after operation, and their replies obtained by telephone from one of the investigators (A. C. Q., A. S.).

Data were analysed using SPSS v6 for Windows statistical package. Chi-square and t tests were used as appropriate. Significance was considered at $P < 0.05$.

Results

In total, 100 consecutive patients were recruited to the study, 50 in the reinforced LMA group (group A) and 50 in the nasotracheal group (group B). There were no significant differences in patient data between the groups (table 1), and there were more females than males.

Table 1 Patient data (mean (range) or number). No significant differences between groups

Total ($n = 100$)	Reinforced ($n = 50$)	Nasotracheal tube ($n = 50$)
Age (yr)	26 (19–42)	26 (17–60)
Sex (M/F)	15/35	Male = 20/30
Teeth extracted	2.5 (1–4)	2.8 (1–4)

There were no significant differences in the incidence of difficulties with positioning of the airway, but in group A, two patients required repositioning of the reinforced LMA which was dislodged in transit from the anaesthetic room to theatre (table 2). There was a significantly greater incidence of epistaxis in the nasotracheal tube group (19 compared with 0; $P = 0.001$) and a higher incidence of partial obstruction in the reinforced LMA group (five compared with no cases: $P = 0.018$).

On fibreoptic examination of the airway during reinforced LMA anaesthesia, we found that in 25 cases the epiglottis was positioned outside the mask and in 33 cases the reinforced LMA was positioned centrally over the larynx. There was no laryngotracheal soiling with blood or debris in group A. Fibreoptic examination of the nasotracheal tube group showed that there were three cases of tracheal soiling with blood, all associated with epistaxis after passage of the tube. Soiling consisted of small spots of blood in the trachea below the tube, but there was no evidence of obstruction. One patient in group B developed bronchospasm after induction resulting in mildly increased airway pressures, which stabilized spontaneously during maintenance with isoflurane.

Desaturation did not occur in either group before or during operation, but in the recovery period saturation occurred most often in group B (six compared with two; ns). Desaturation was transient and Sa_{O_2} did not decrease to less than 90% with supplementary oxygen 4 litre min^{-1}. After operation there were no other problems with airway management, but the recovery staff reported a qualitatively superior recovery with the reinforced LMA.

There was an 88% reply rate to the questionnaire which was distributed evenly between the groups (table 3). There was no significant difference between the groups in the incidence or severity of postoperative headache, nausea, vomiting, sore throat, thirst, jaw pain, hoarseness or preoperative anxiety. Overall there was a low incidence of nausea (75% experienced no nausea) together with a very low incidence of vomiting (5.7%). After operation, sore throat occurred in 58.9% of patients which was mostly of a mild nature. The majority (60–70%) of patients experienced moderate or severe jaw pain after operation.

Comparing overall satisfaction with the airways, anaesthetists felt that both tubes provided an excellent airway in the majority of patients (group B,

Table 2 Intraoperative observations. *Dislodged in transit from anaesthetic room to theatre

	Reinforced LMA ($n = 50$)	Nasotracheal tube ($n = 50$)	P

	Fair	2
Nasotracheal tube	Excellent	50
($n = 50$)	Good	0
	Fair	0

49 compared with group A, 42) (table 4). The reinforced LMA provided only a fair airway in five patients which accounts for the cases of partial obstruction. On no occasion was either airway described as poor. Surgical satisfaction with access was noted as excellent in the majority of patients (group B, 50 compared with group A, 43); none considered access poor in any case.

Discussion

The purpose of this study was to assess conditions provided by the reinforced LMA during oral surgery compared with nasotracheal intubation. Although we are aware of its widespread use in this area, we felt it was important to fully study the advantages and disadvantages of the technique and confirm its safety. The use of the LMA in various oral surgical procedures has been studied extensively but the following features have not been elucidated fully: inspection of the position of the mask and obstruction of the airway, and perioperative problems, including airway access, postoperative sore throat and nausea and vomiting, compared with nasotracheal intubation. Our results showed that the reinforced LMA may be used safely in place of nasotracheal intubation during anaesthesia for extraction of wisdom teeth. The mask provided a clear and effective airway in 90 % of cases until emergence from anaesthesia and also provided good surgical access. It is worth noting that this study was carried out at a University Dental Institute where many inexperienced trainee oral surgeons were performing the extractions but who coped well with the reinforced LMA in the oral cavity.

We inserted the reinforced LMA according to the manufacturer's instruction but initially found the technique moderately difficult, presumably because of lack of experience with the technique. A recent article examining 1500 LMA insertions by a single anaesthetist [6] illustrates this learning curve—there was an improvement in the author's technique after the first 750 insertions. The reinforced LMA was not taped to the face during bilateral procedures to enable the surgeon to move the tubing of the reinforced LMA if access was poor or on changing operating sides (it was more troublesome to attempt to remove tape under the surgical drapes halfway through the procedure). No repositioning of the reinforced LMA was required as a result of obstruction during operation. The need for repositioning on two occasions occurred on transit from the anaesthetic room to theatre where the mask was accidently pulled out. Both masks were repositioned easily before commencing surgery.

In the five reinforced LMA cases in which partial obstruction occurred, this was caused during downward pressure on the mandible as the forceps were applied round the tooth to remove it from its socket. Unfortunately we were unable to assess the position of the reinforced LMA at that point although we can speculate that it may have been pushed up more against the proximal anterior laryngeal wall. All obstructions were corrected by counter pressure on the mandible. Overall the rate of obstruction was similar to that found previously [7–9] but there was no correlation with the position of the reinforced LMA over the cords with respect to the epiglottis and the incidence of obstruction.

Interestingly three cases in the nasotracheal tube group were difficult to position, indicating that the standard technique was not without problems. Also, there was a high incidence (38 %) of epistaxis and the only three cases of laryngotracheal soiling occurred in this group. However, we did not pretreat the nasopharynx with a vasoconstrictor.

We were surprised that in the reinforced LMA group there was a high incidence of severe or moderate sore throat compared with the nasotracheal tube group, contrary to previous findings [10]. In part this may have reflected our inexperience with the reinforced LMA (proportionately more sore throats early in the study) but it is more likely to be caused by a gauze dental pack in the pharynx. We deliberated on whether or not the pack was necessary as it has the potential to displace the reinforced LMA leading to obstruction and may be superfluous as the LMA affords excellent airway protection from secretions from above (but not below) [11]. However, given the degree of soiling of some of the packs we preferred to use them and so minimize blood-/secretions entering the stomach. This may be reflected in the low incidence of postoperative nausea and vomiting given the young age of the patients, the high proportion of females, the type of surgery and the fact that no antiemetics were prescribed.

Isoflurane waste gas exposure during general anaesthesia: the laryngeal mask compared with tracheal intubation

K. H. HOERAUF, C. KOLLER, W. JAKOB, K. TAEGER AND J. HOBBHAHN

Summary

We have compared exposure to isoflurane while using the laryngeal mask airway (LMA) during anaesthesia under positive pressure ventilation with exposure while using tracheal intubation. Trace concentrations of isoflurane were measured directly using a highly sensitive photoacoustic infrared spectrometer (Bruel and Kjaer 1302, Denmark) during general anaesthesia in 20 eye surgery procedures. Measurements were made at six locations (three personnel-related, three leakage-related) in the operating theatre. Despite some high isoflurane values (greater than 2000 ppm at one leakage-related measurement point) all measured values at the personnel-related points were low (the majority were less than isoflurane 2 ppm). In the LMA group, mean trace concentrations were slightly higher than in the tracheal tube (ET) group. Mean exposure to isoflurane, expressed as median (range) related to anaesthetic administration, was highest for the auxiliary nurse (0.64 (0.22–26.89) ppm for the LMA compared with 0.31 (0.02–1.07) ppm for the tracheal tube), followed by the anaesthetist (0.50 (0.28–2.28) ppm for the LMA compared with 0.35 (0.02–0.73) ppm for the tracheal tube) and the surgeon (0.36 (0.20–3.93) ppm for the LMA compared with 0.29 (0.01–0.50) ppm for the tracheal tube). We conclude that the use of the LMA in patients undergoing ventilation is not associated necessarily with high concentrations of isoflurane in a modern working environment (*Br. J. Anaesth.* 1996; **77**: 189–193)

Key words

Anaesthetics volatile, isoflurane. Anaesthesia, general. Equipment, masks anaesthesia. Intubation tracheal.

American and most European public health authorities recommend threshold values (table 1) for occupational exposure to trace concentrations of volatile anaesthetic agents. The National Institute for Occupational Safety and Health (NIOSH) recommends that occupational exposure to halogenated anaesthetic agents, when used as the sole anaesthetic, should not exceed 2 ppm, expressed as time-weighted averages (TWA) [1]. In European countries, recommended threshold values for these agents range from 2 to 20 ppm. Most of the national exposure standards are related to an 8-h TWA, although the NIOSH values relate to TWA over the period of anaesthetic administration.

The laryngeal mask airway (LMA) is a relatively new device for management of the airway during general anaesthesia [2]. Brain and colleagues stated that the LMA was gas-tight in positive pressure ventilation up to 30 cm H_2O [3]. A recent study has shown mean leak values of up to 27% of the inspired volume during LMA use and up to 4% during tracheal intubation, both under positive pressure ventilation (IPPV) [4]. Such high leakage during laryngeal mask anaesthesia could result in pollution of the operating theatre.

To date, data on occupational exposure of operating theatre personnel to theatre pollution during LMA anaesthesia have been available only for nitrous oxide. Lambert-Jensen, Christensen and Brynnum reported nitrous oxide exposure, comparing spontaneous and controlled ventilation using the LMA [5], and Sarma and Leman reported low nitrous oxide concentrations during spontaneous breathing [6].

In this study we measured exposure to isoflurane while using the LMA during anaesthesia with IPPV in an operating theatre with air conditioning and scavenging systems conforming to NIOSH recommendations, and compared these concentrations with exposure while using tracheal intubation under identical conditions. In contrast with earlier studies, staff exposure (surgeon, anaesthetist and auxiliary nurse) was recorded directly at the subject's mouth, and three static points (operation area, mouth of the patient and reservoir bag of the anaesthesia machine) related to potential leakage sources were also measured.

Methods and materials

STUDY POPULATION

We studied 20 patients undergoing ophthalmological procedures under general anaesthesia in a prospective, randomized study. The treatment assignments (tracheal tube or LMA) were contained in sequen-

tially ordered sealed envelopes, which were opened before induction of anaesthesia. Ten patients received an LMA (group 1) and 10 patients a tracheal tube (ET = group 2). The study did not influence routine patient management. Induction, maintenance and emergence from anaesthesia were performed in the operating theatre. Anaesthesia was induced with propofol 1.5–3.0 mg kg^{-1} (until loss of eyelash reflex) and maintained with i.v. alfentanil and isoflurane, and 65% air in oxygen. Administration of isoflurane as the sole volatile anaesthetic agent was started after insertion of either the LMA or tracheal tube. A size 4 laryngeal mask was inserted by one of two anaesthetists using the technique recommended by the manufacturer. Tracheal RAE tubes (Mallinckrodt Medical, Germany) with an internal diameter of 7.5 mm or 7.0 mm were used for male and female patients, respectively. Fresh gas flow was 4 litre min^{-1}. A new low-leakage [7] Sulla 808 V (Draeger, Germany) was used as the anaesthesia machine. Inspiratory isoflurane concentration and ventilation pressures were recorded using a Capnomac infrared analyser (Datex, Finland). The waste gas outlets of both the anaesthesia machine and the infrared analyser were connected to the central scavenging system (60 litre min^{-1}) of the hospital.

WORKPLACE DESCRIPTION

The air volume of the operating theatre in this study was 130 m^3. Ventilation and air conditioning systems were separate from those serving other rooms of the hospital. Connections between the recovery room, other operating theatres and the operating theatre of the study did not exist. Air conditioning was performed by a laminar flow system producing an air change rate of 20 changes per hour (2600 $m^3 h^{-1}$) without recirculation. The location of the area below the air conditioning vents is shown in figure 1.

SAMPLING STRATEGY

Trace concentrations of isoflurane were measured directly using a highly sensitive photoacoustic infrared spectrometer (Bruel and Kjaer 1302, Denmark). The lower detection limit for isoflurane was 0.009 ppm and accuracy was within ±2% of the measured value. Gas was sampled under ambient pressure conditions using 8-m lengths of polyamide tubes (Siegle, Germany). Air samples were obtained sequentially at six locations (fig. 1) in the operating theatre using a Bruel and Kjaer 1303 multipoint sampler. Three measurement points were personnel-related: AN = anaesthetist, S = surgeon, AX = auxiliary nurse. Sampling tubes were fitted at the operating theatre personnel's masks, and therefore air sampling was accomplished within the breathing zone. The other three sampling points were at the sites of potential leaks: OP = operation area, M = mouth of the patient, AM = reservoir bag of the anaesthesia machine. Data from the infrared spectrometer were recorded continuously using a personal computer system. Cuff pressure in the ET group was kept within the range of 20–30 cm H_2O using an Endotest (Ruesch, Germany) manometer.

MATHEMATICS

To calculate mean exposure during administration of anaesthetic, concentrations were calculated for each anaesthetic from the area under the curves derived from intermittent measurements. These mean trace concentrations for each anaesthetic and all locations are plotted in figure 2. Median and range were calculated for each location and group and presented in table 3. Between-locations and between-group comparisons were performed using the Wilcoxon test ($P < 0.05$).

Results

Both anaesthetists were experienced in inducing and maintaining general anaesthesia using the LMA or tracheal tube. The masks were introduced successfully on the first or second attempt.

Mean values for exposure time during anaesthesia, ventilation pressures, inspiratory isoflurane concentration and patient data were comparable in both groups (table 2). Median and ranges of mean trace concentrations of isoflurane in both groups are shown in table 3. Distributions of mean trace concentrations of the individual anaesthetic procedures are illustrated in figure 2.

Table 3 Median (range) mean trace concentrations related to the time over the duration of anaesthetic administration at the different measurement points in the operating theatre. Values are in parts per million (ppm). Significant differences (P < 0.05): *within leakage-related values; †between groups

Location	LMA group	ET group
Personnel-related values		
Anaesthetist (AN)	0.50 (0.28–2.28)	0.35 (0.02–0.73)
Surgeon (S)	0.36 (0.20–3.93)	0.29 (0.01–0.50)
Auxiliary nurse (AX)	0.64 (0.22–26.89)	0.31 (0.02–1.07)
Leakage-related values		
Operating area (OP)	2.54 (0.22–31.02)	0.32 (0.06–0.76)
Patient's mouth (M)	32.81 (0.46–2150)*†	0.89 (0.32–11.42)
Anaesthesia machine (AM)	0.37 (0.26–3.36)	0.30 (0.05–0.92)

In the ET group, all *personnel-related* mean trace concentrations were less than isoflurane 2 ppm. In the LMA group at the locations of both the anaesthetist and the surgeon, one of 10 means exceeded this value. In the position occupied by the auxiliary nurse, three of 10 values exceeded 2 ppm. These higher values occurred during anaesthetic procedures in which values greater than isoflurane 100 ppm at the patient's mouth were measured. Any statistically significant differences in mean trace concentrations within the personnel-related measurement points and between the ET and LMA group were detected ($P < 0.05$).

Leakage-related values indicated that the artificial airway was the main leakage source in both groups. Trace concentrations were higher and variation was greater in the LMA group than in the ET group. The difference between the concentrations was statistically significant between the ET and LMA groups, and within the leakage-related LMA values at point M. Trace concentrations at locations AM and OP were comparable between the groups and within the leakage-related values.

Discussion

Some studies suggest that chronic exposure to trace concentrations of volatile anaesthetics may result in various forms of untoward health responses [8, 9]. The limitations of epidemiological studies have been discussed [10, 11]. Because of flaws in the epidemiological investigations and a lack of data concerning dose relationships, it has not been possible to establish an aetiological connection between such untoward health responses and waste anaesthetic gases [12].

To maintain low occupational exposure, NIOSH has also outlined a number of criteria for the workplace [1]. These criteria were fulfilled in this study. (1) The anaesthesia machine was connected to a central high-flow scavenging system (60 litre min^{-1}). (2) Leakage from the breathing system of a typical Draeger Sulla 808V was 22.8 ml min^{-1} [7],

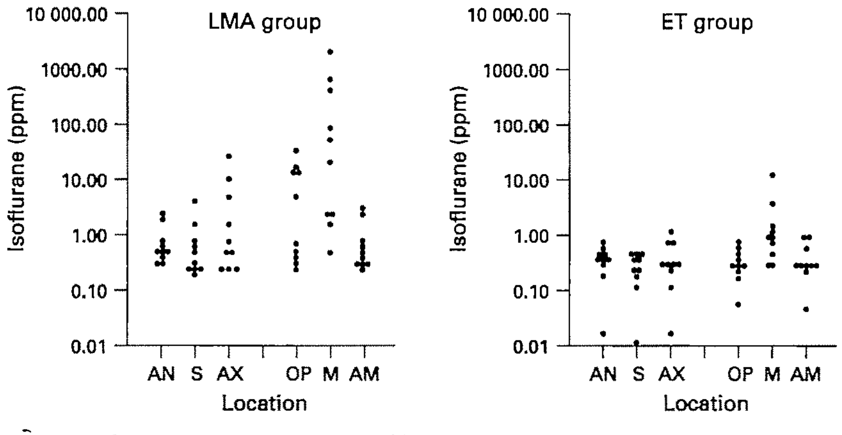

Figure 2 Distribution of mean trace concentrations of isoflurane at different locations (AN = anaesthetist, S = surgeon, AX = auxiliary nurse, OP = operating area, M = mouth of patient, AM = anaesthesia machine) in the LMA and ET groups.

far below the leakage value of 150 ml min^{-1} proposed by the Draft European Standard *Anaesthetic Workstations and Their Modules*. (3) Anaesthetic gas flow was started after insertion of the artificial airway (LMA or tracheal tube). Intermittent face mask ventilation with isoflurane was not performed. (4) Room ventilation comprised 20 changes per hour, with no air being recirculated. (5) The waste gas outlet of the anaesthetic gas monitor, a potential source of contamination [13], was connected to the hospital's central scavenging system (60 litre min^{-1}).

Trace concentrations of anaesthetics may be measured either off-line by gas chromatography or on-line using direct reading instruments. The system used in this study has some advantages over other direct reading instruments such as the MIRAN series. Using photoacoustic infrared spectrometry, detection levels are lower and accuracy is greater because of the possibility of cross-compensation for other gaseous substances present in the operating theatre. The Bruel and Kjaer 1302 photoacoustic infrared spectrometry system allows detection limits as low as isoflurane 0.009 ppm, with an accuracy of ±2% [14, 15].

Mean trace concentrations were calculated for each anaesthetic from the area under the curves derived from the intermittent measurements made by the measurement system, reflecting exposure during the period of anaesthetic administration neglecting, for example, intervals between operations. We believe this method may reflect accurately occupational exposure during anaesthesia; on the other hand, corrections to an 8-h working day can be performed easily or could be adapted to individual working shift conditions.

Leakage from the artificial airway appeared to be the main source of occupational exposure. In the LMA group, 60% of the mean values measured near the patient's mouths were greater than isoflurane 10 ppm. Peak concentrations exceeding 100 ppm were recorded in some cases, but there was no relation to higher ventilatory pressures in these cases. In the ET group, in one patient, isoflurane mean values exceeded 10 ppm. Variation of the mean values was less for the ET group than for the LMA group.

Trace concentrations recorded at the reservoir bag of the anaesthesia machine were all less than 5 ppm, which is consistent with the reportedly low leakage rate from the breathing system of this machine [7].

As expected with this type of surgery (eye surgery), because of the proximity of the measurement point "OP" to the main leakage source, point "M", mean values recorded at point "OP" probably do not reflect a specific contribution to air contamination.

Despite the high trace concentrations near the patient's mouth, most personnel-related mean trace concentrations were less than the strict NIOSH limit of 2 ppm of isoflurane. Higher mean trace concentrations (three of 10) at the position of the auxiliary nurse occurred during anaesthetic procedures in the LMA group in which substantial leakage from the patient's mouth was detected. In these patients, at the locations of both the anaesthetist and the surgeon, only one of 10 mean values exceeded 2 ppm. The higher levels for the auxiliary nurse could be explained by the position outside the main airflow of the air conditioning system and air movement from the laminar air flow field to the air exhausts in the corners of the operating theatre (fig. 1). The workplaces of the surgeon and anaesthetist, however, were within the main air flow, which probably explains why their mean concentrations were mainly less than 2 ppm in both groups.

With tracheal intubation, values of isoflurane in our study were less than those of other studies, which have reported concentrations of isoflurane 2.4–12 ppm [16], 3–11 ppm [17] and 13.4–21.0 ppm [18]. The higher values in these studies may be a result of less effective air conditioning systems, lack of a scavenging system or higher leakage from the anaesthesia machines [16–18].

Until now occupational exposure during general anaesthesia using the LMA has been measured only for nitrous oxide. Lambert-Jensen, Christensen and Brynnum found a higher, but non-significant difference in trace concentrations with controlled ventilation compared with spontaneous breathing. Nitrous oxide concentrations were 7.0–24.0 ppm under controlled ventilation and 7.5–18.4 ppm during spontaneous breathing [5]. Sarma and Leman reported that the LMA resulted in minimal theatre pollution during spontaneous ventilation. Nitrous oxide peak level ranged from 15 to 37 ppm [6].

A previous study on tracheal intubation and nitrous oxide pollution performed under identical working place conditions showed median trace concentrations at the personnel-related measurement points of 11.4–19.6 ppm [19].

We conclude that anaesthesia using the LMA in patients undergoing ventilation may be associated with high concentrations of isoflurane near the patient's mouth because of higher leakage rates. Using an effective high-flow scavenging system and air conditioning equipment that provided 20 changes of air per hour without recirculation, and a low-leakage anaesthesia machine, mean trace concentrations in the working environment may be almost as low as those associated with anaesthesia using tracheal intubation. Under other circumstances (e.g. lower air change rates), trace concentrations of isoflurane may be higher.

Ventilatory effects of eltanolone during induction of anaesthesia: comparison with propofol and thiopentone†

H. J. SPENS AND G. B. DRUMMOND

Summary

We recorded the ventilatory effects of eltanolone 0.75 mg kg^{-1}, propofol 2.5 mg kg^{-1} and thiopentone 4 mg kg^{-1} at induction of anaesthesia in 76 unpremedicated patients, aged 18–65 yr. Measurements were made using a pneumotachograph incorporated between a close-fitting face mask and a T-piece delivering 35% oxygen. Eltanolone caused significantly less apnoea than propofol (incidence 57% *vs* 100%) and less reduction in ventilation than propofol (median maximum decrease 4.8 *vs* 7.8 litre min^{-1}), but the differences between eltanolone and thiopentone were smaller and generally not significant. Ventilatory frequency was maintained well in the eltanolone group. (*Br. J. Anaesth.* 1996; **77**: 194–199).

Key words

Anaesthetics i.v., eltanolone. Anaesthetics i.v., propofol. Anaesthetics i.v., thiopentone. Ventilation, effects. Ventilation, apnoea.

The anaesthetic properties of some steroids have been recognized for more than 50 yr [1]. However, the development of these compounds for clinical use has been slow, because of adverse events with water-soluble agents [2–4] and the lack of a suitable solvent for lipid-soluble agents.

Eltanolone (3α-hydroxy-5β-pregnane-20-one, pregnanolone) has been known as a potent anaesthetic since 1957 [5]. An emulsion formulation of eltanolone, with the agent dissolved in the lipid phase of an oil–water emulsion, is now available (Careltan, Pharmacia). Potential advantages of this new drug, in comparison with currently available induction agents, include a high therapeutic ratio and lack of pain on injection. In addition, preliminary studies have reported less apnoea [6, 7], in keeping with findings with earlier steroid induction agents [8, 9].

Lack of depression of ventilation is advantageous in anaesthesia if neuromuscular blocking agents are not used, allowing smooth transition from i.v. to inhalation anaesthesia and helping to prevent hypoxia. The aim of this study was to investigate the ventilatory effects of eltanolone at induction of anaesthesia, and to compare these effects with those of propofol and thiopentone.

Patients and methods

After obtaining local Ethics Committee approval and written informed consent, we studied 76 ASA I and II patients, of both sexes, aged 18–65 yr, undergoing elective surgery. We excluded patients who were more than 50% above ideal weight for height (Metropolitan Life Insurance Company tables), pregnant, who had significant respiratory disease, anaesthetic drug allergy, who abused alcohol or other substances or who were receiving any medicines which might affect ventilation. Patients received no premedication and were allocated randomly to receive eltanolone 0.75 mg kg^{-1}, propofol 2.5 mg kg^{-1} or thiopentone 4 mg kg^{-1} for induction of anaesthesia. These doses have been shown to be approximately equipotent [7, 10].

After arrival in the anaesthetic room an i.v. cannula was inserted. Inductance bands were positioned around the chest and abdomen and connected to a respiratory inductance plethysmograph. The signals, representing dimensional changes in the rib cage and abdomen with respiration, were recorded using commercial respiratory monitoring software (Cardas, version 2.07 advanced, Oxcams, Oxford), running in MS-DOS (version 6.20), onto a lap-top computer. These bands allowed detection of upper airways obstruction by comparison of chest wall movement and respired volumes. Patients lay on a mattress filled with polystyrene beads that was made rigid to prevent body movement (Vac-Pac, Howmedica). Patients breathed 35% oxygen from a T-piece, through a screen pneumotachograph (F100L, Mercury Electronics) and a tight-fitting face mask with a wide pneumatic seal (Downs CPAP mask No. 9002, Vital Signs Inc., NJ, USA), held in place with both hands by the anaesthetist. The pneumotachograph was connected to a differential pressure transducer (±10 mm H_2O), Furness) and the resulting flow signal was also recorded. The system was calibrated in the laboratory using a series RT200 calibration analyser (Timeter Instrument Corporation, Missouri, USA) and was linear up to 40 litre min^{-1}. Immediately before each study, the

†Presented in part at the 3rd Congress of the European Society of Anaesthesiologists, Paris, April 29–May 3, 1995 (*British Journal of Anaesthesia* 1995; 74 (Suppl. 1): A164).

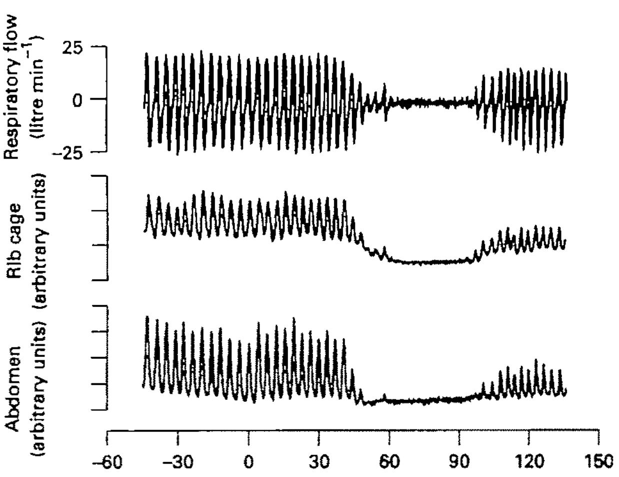

Figure 1 Part of a typical recording, with respiratory flow and dimensions of the rib cage and abdomen. The induction agent was given over 30 s, starting at time 0.

calibration was checked against a flowmeter (its accuracy had also been verified in the laboratory) and was considered acceptable if the error was less than ±5%. A pulse oximeter (Ohmeda Biox 3700) was used to measure oxygen saturation and heart rate and these signals were also recorded on the computer.

After a period of 3–5 min of stable breathing, the induction agent was administered over 30 s. Lignocaine 10 mg was mixed with propofol to prevent pain on injection. The moment of loss of consciousness was noted from when the patient dropped a metal rod held between the thumb and index finger. If consciousness was not lost within 120 s further anaesthetic was given and the patient was withdrawn from the study. The patient's jaw was supported gently by the anaesthetist to prevent upper airway obstruction. Recordings were continued for 4 min from the start of induction or until the patient showed signs of arousal when a further dose of induction agent was administered. Any adverse events which occurred, including apnoea, were noted. After completion of this study, anaesthesia was continued as appropriate for clinical management. A tracing of part of a typical study is shown in figure 1.

The flow signal was then analysed by a locally written computer program which calculated breath by breath values for tidal volume (V_T), respiratory frequency (f), inspiratory time (T_I) and expiratory time (T_E). Mean values over 30 s were calculated every 30 s from the start of administration of the induction agent. Minute ventilation (V_E) was then obtained from the product of V_T and f. A stable 30-s period, approximately 2 min before the start of induction, was used to calculate control values.

Adverse events during anaesthesia were noted. All patients were visited approximately 24 h after operation and returned a questionnaire 2 weeks later to determine if any side effects had occurred. They were asked specifically about the severity and duration of nausea and vomiting, dizziness or lightheadedness, headaches, sore throat, rashes or drip site inflammation, muscle pains and cough.

Data were analysed using the Minitab statistical package (release 8.2), running in MS-DOS (version 6.20). Non-parametric tests of significance were used to compare the three groups and changes from baseline (Kruskal–Wallis, Mann–Whitney, Wilcoxon signed rank sum and chi-square as appropriate). With 23 patients per group the estimated power of the study to detect a difference in ventilation of 2 litre min^{-1} at a significance level of 0.05 was 0.8.

Results

Of the 76 patients recruited, results were available for analysis from 69, 23 per group. Two patients in the propofol group were excluded because of study violations, two patients (one eltanolone, one propofol) developed upper airway obstruction after induction of anaesthesia, shown by normal or increased chest wall movements with absent or reduced flow, and therefore were excluded, data from two patients in the thiopentone group could not be analysed because their breathing patterns were too irregular, and one patient's operation was cancelled after randomization to receive eltanolone.

The characteristics of those included are shown in table 1. The propofol group contained more males and the thiopentone group more females than the eltanolone group, with a corresponding bias in height and weight.

Induction of anaesthesia was successful in all patients, and the time from the start of administration of the induction agent to loss of consciousness was similar in the three groups (means 45.8, 43.5 and 45.3 s in the eltanolone, propofol and thiopentone groups, respectively).

The incidence of apnoea and the median duration of absent breathing are shown in table 2. Differences

Table 1 Patient characteristics (mean (SD or range) or number)

	Eltanolone (n = 23)	Propofol (n = 23)	Thiopentone (n = 23)
Age (yr)	37.1	37.5	37.3
	(18–58)	(22–54)	(20–64)
Height (cm)	172	175	169
	(9.4)	(8.4)	(9.4)
Weight (kg)	70.8	73.2	65.5
	(9.2)	(10.5)	(12.6)

Table 3 Respiratory variables for the three groups for each time period (median (quartiles)). Statistical differences ($P < 0.05$) between drug groups are indicated (* eltanolone *vs* propofol, † eltanolone *vs* thiopentone, ‡ propofol *vs* thiopentone). All values of minute volume and tidal volume were significantly reduced from baseline from 60 s onwards. Frequency was reduced significantly from baseline at 60–120 s in the propofol group, and at 60–90 s in the thiopentone group. From 150 s in the eltanolone group, 180 s in the propofol group and at 240 s in the thiopentone group, ventilatory frequency was significantly greater than baseline

between the eltanolone and propofol groups were highly significant ($P < 0.01$) but differences between the eltanolone and thiopentone groups were not.

Table 3 shows the respiratory variables measured. Baseline ventilation and tidal volume were greater in patients who received propofol, probably because of the preponderance of males in this group. In all groups there was a significant reduction from baseline in both minute volume and tidal volume from 60 s onwards. The maximum reduction in minute ventilation in the eltanolone group was significantly less than that in the propofol group (median 4.8 *vs* 7.8 litre min^{-1}), but was not significantly different from the thiopentone group (6.1 litre min^{-1}). Similarly, tidal volumes were depressed to a greater extent in the propofol group.

Ventilatory frequency, however, exhibited a somewhat different pattern. In the eltanolone group it did not decrease below baseline values, unlike the propofol and thiopentone groups where it was significantly below baseline at 60–120 s and 60–90 s, respectively. The difference between eltanolone and propofol was significant at 60–150 s. In all groups ventilatory frequency increased above baseline towards the end of the study and this effect was most marked in the eltanolone group and least in the thiopentone group.

We also analysed the minimum value of minute ventilation in each patient after injection. The median minimum minute ventilation was 3.3 litre min^{-1} (interquartile range 0–4.5 litre min^{-1}) in the eltanolone group, 0 (0–0.6) litre min^{-1} in the propofol group and 0.7 (0–2.4) litre min^{-1} in the thiopentone group. The minimum minute ventilation tended to be reached later in the eltanolone group (median 90 s from the start of injection) than in the two other groups (median 60 s). The difference in treatment effect between eltanolone and propofol was highly significant ($P < 0.01$), but the difference between eltanolone and thiopentone was not ($P = 0.09$).

Summary spirograms have been drawn to allow comparison of the pattern of breathing after each drug, using baseline measurements and values at 180 s (fig. 2). This time period was chosen for analysis because it was the first after injection where spontaneous respiration had restarted in most patients. Inspiratory time (*T*I) was reduced more in the eltanolone and propofol groups at 180 s compared with the thiopentone group ($P < 0.05$), corresponding to the increase in ventilatory frequency observed in these patients. Inspiratory drive, expressed by the gradient of the inspiratory line (*V*T/*T*I), was reduced more in the propofol group than in the eltanolone or thiopentone groups, but this difference was not significant.

There were no serious adverse events during the study, but several minor side effects were noted. Table 4 summarizes the adverse events during anaesthesia. Involuntary movement occurred in 10 patients who had received eltanolone and in four who had received propofol. These were graded as moderate in three of the eltanolone group and mild in the remainder. They lasted between a few seconds and several minutes, terminated spontaneously in all

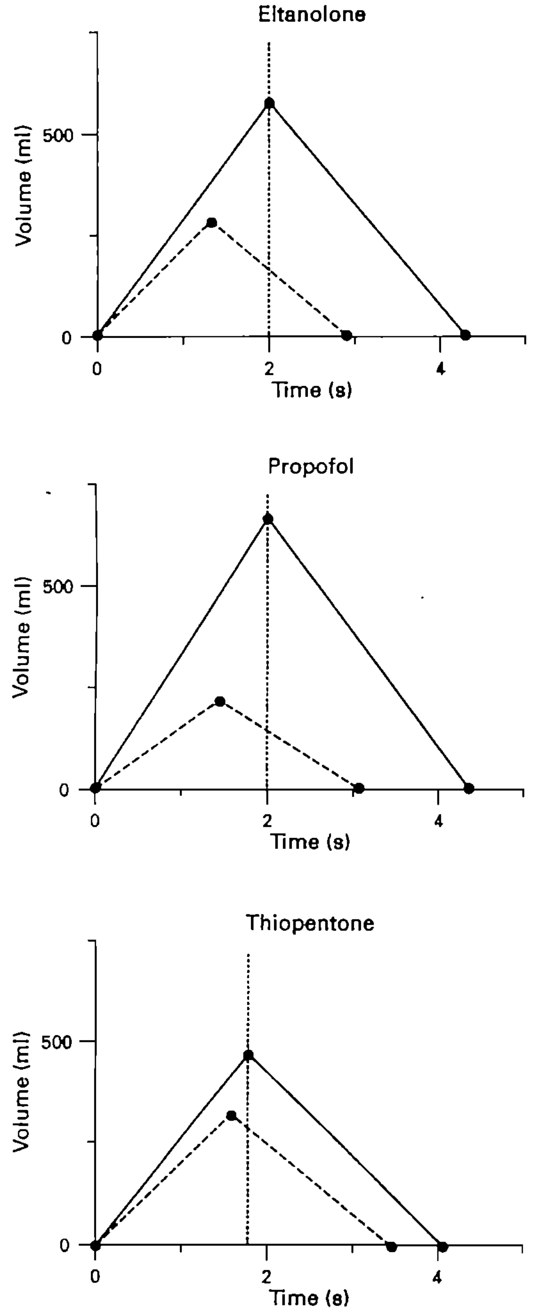

Figure 2 Summary spirograms for each drug; —— = baseline, - - - = 180 s. V_T/T_I was relatively well preserved with eltanolone and thiopentone compared with propofol, while T_I was better preserved in the thiopentone group.

cases and did not cause any clinical difficulty. Additionally, two patients in the eltanolone group developed hypertonus of the neck or upper limbs.

Flushing occurred in two patients in the eltanolone group and in one patient in each of the other treatment groups. However, in all cases this occurred after the end of the study and was related temporally to the administration of other drugs known to release histamine rather than administration of the induction agent.

Six patients who had received eltanolone coughed during the anaesthetic, compared with two who had received propofol and three who had received thiopentone. Additionally, one patient in the eltanolone group developed laryngospasm and one patient in the propofol group developed bronchospasm. However, these adverse events were not generally attributable to the induction agent, but usually occurred if the inspired concentration of isoflurane was increased rapidly. Oxygen saturation decreased to less than 85% as a result of coughing in one patient after propofol, and because of prolonged apnoea in five patients who received propofol and one patient who received thiopentone.

Table 4 Incidence (%) of adverse events during anaesthesia (all patients)

	Eltanolone ($n = 24$)	Propofol ($n = 26$)	Thiopentone ($n = 25$)

Other	6 (25)	6 (23)	7 (28)

Tachycardia (> 100 beat min^{-1}) was more common after eltanolone, occurring in 10 patients compared with only two after propofol and none after thiopentone. However, this was probably directly attributable to eltanolone in only two cases, with insufficient depth of anaesthesia and other anaesthetic agents being more likely causes in all other cases.

Adverse events reported after operation are shown in table 5. Nausea and vomiting were the most frequently described side effects, with a greater incidence reported in the eltanolone and thiopentone groups than in the propofol group, but the differences were not significant. Similar numbers of patients in each group complained of dizziness, while the incidence of all other side effects was low and distributed fairly evenly between the three groups.

Discussion

Our results confirmed that induction of anaesthesia with eltanolone in unpremedicated patients produced much less depression of ventilation than an equipotent dose of propofol, in terms of reduction of minute volume, incidence of apnoea and duration of absent breathing. Ventilatory depression with eltanolone was also less than that with thiopentone, but this was significant only at 60 s, with no significant difference in either the maximum reduction or minimum minute ventilation recorded. Ventilatory frequency was better maintained with eltanolone than with either of the two drugs, and was increased significantly from baseline from 150 s onwards.

A larger sample size might have revealed a difference between eltanolone and thiopentone. When we designed the study we calculated that a sample size of 69 would give a power of 0.8 to detect a difference of 2 litre in minute ventilation, at a significance level of 0.05, given an SD for ventilation of 2.2 litre min^{-1}. However, there was considerable variation in the reduction of ventilation, and the power of the study to detect a real difference in ventilation of 2 litre min^{-1} was only approximately 0.75.

We found that the baseline value of minute volume was significantly greater in the propofol than in the eltanolone and thiopentone groups (median 8.2 *vs* 7.9 and 7.2 litre min^{-1}, respectively). This was probably because of the difference in sex distribution between the three groups, and we do not consider the difference to be clinically important.

In any study of ventilation using a face mask there is potential for measurement error for several reasons. Unrecognized mask leaks are one possible source of inaccuracy. To minimize this we used a face mask with a wide pneumatic rim, applied water soluble jelly to improve the seal if facial stubble was present, and held the mask firmly in place using two hands, allowing manual detection of escaping gas. Use of an end-tidal carbon dioxide monitor in a few patients showed normal waveforms and end-tidal values, confirming our belief that significant gas leaks did not occur. The measurement apparatus may itself induce changes in ventilatory pattern [11], but this effect is least when a face mask with high fresh gas flow is used, as in our system, and is less relevant when comparing groups as all patients would be equally affected. We did not make any recordings of arterial pressure during the study as we believe that inflation of a pneumatic cuff on the arm may have been sufficiently stimulating to affect respiratory pattern.

Further investigation of eltanolone may provide different estimates of the relative potency, which could alter the interpretation of our results. Also, although administration of a pre-calculated bolus dose of induction agent over approximately 30 s is common clinical practice, other methods, for example less rapid administration to a clinical end-point such as cessation of counting, could result in different dose requirements and ventilatory effects [12–14].

Direct comparison of our results with other studies is difficult because of both the variable doses administered and the different premedications used in earlier work. Additionally, our study is the first which has been designed to examine specifically the ventilatory effects of eltanolone, and therefore the only previous eltanolone data available for comparison are observations of apnoea.

Using eltanolone 0.75 mg kg^{-1} we found that 30 % of patients were apnoeic for greater than 30 s, with 13 % being apnoeic for more than 60 s. This is a greater incidence than reported by many earlier authors [6, 7, 15, 16] but, except for one study [16], smaller doses of eltanolone were used. After a prior dose of fentanyl, and a dose of 0.59–0.89 mg kg^{-1}, given over a range of times, Myint, Peacock and Reilly [12] reported that 37 % of their patients were apnoeic for more than 30 s. All patients studied by Kallela and colleagues [17] using eltanolone 0.8 mg kg^{-1} were apnoeic for more than 60 s, probably because of the generous dose of alfentanil given before induction.

There are some data available on the ventilatory effects of earlier steroid induction agents, and in general the pattern we have seen with eltanolone is similar. Hall, Whitwam and Morgan [18], using Althesin 50 and 100 µl kg^{-1} after either diazepam or papaveretum premedication, found an incidence of apnoea of 41 %, lasting 8–102 s, compared with an incidence of 56.5 %, lasting 4–119 s, in our study. Additionally, they described a significant reduction in minute ventilation at 2 and 3 min after induction of anaesthesia with Althesin, with an increase in ventilatory frequency above baseline after 3 min in the non-opioid groups, which are similar to our own observations with eltanolone. However, Campbell and colleagues [19], using Althesin 100–150 µl kg^{-1} in unpremedicated patients, did not observe apnoea, but described a similar increase in ventilatory frequency. Savege and colleagues [8], using Althesin 50 µl kg^{-1}, also found an increase in ventilatory frequency after a period of apnoea averaging 23 s. With minaxolone 0.4 mg kg^{-1} [9], a similar picture was seen, with a 25 % incidence of apnoea of short duration, an increase in ventilatory frequency in the non-opioid group, and a decrease in minute ventilation.

Our study confirms earlier work suggesting that both propofol and thiopentone are ventilatory depressants [8, 20–23]. However, in general, we demonstrated a greater effect than these earlier studies, in spite of the similar or lower doses we used and the fact that our patients were unpremedicated. The reasons for this are unclear, but the higher frequency of observations which we used, the different measurement techniques and the lower baseline ventilation in some of these studies may all have contributed. Previous reports comparing propofol with thiopentone conflict as to whether or not a difference exists between their ventilatory effects; our results suggest that propofol is a more potent respiratory depressant than thiopentone.

The increase in ventilatory frequency found towards the end of our study when anaesthetic depth was presumably less, is consistent with previous work using a variety of agents [8, 9, 18, 20, 24–26]. The mechanism of this effect is uncertain, but it has been postulated that increased excitability of the inspiratory "off-switch" is responsible [24]. Some steroid hormones are known to be respiratory stimulants [27] which may contribute to the enhanced effect we found with eltanolone; however the similarity of this augmentation to that seen with propofol, when respiration restarts, raises the possibility that the lipid emulsion itself may contribute.

We conclude that the modest ventilatory depression seen after induction of anaesthesia with eltanolone may be useful in allowing a smooth transition to inhalation anaesthesia and may also indicate a role in sedation. The only frequent side effect was involuntary movement, but this was never troublesome and should not affect the value of this new agent.

Effect of anaesthesia on lung function in children with asthma

H. A. MAY, R. L. SMYTH, H. C. ROMER, P. H. MARTIN, A. R. BOWHAY AND D. P. HEAF

Summary

Spirometry was performed before operation, soon after recovery ("early") and the day after ("late") general anaesthesia for elective surgery in 20 children with asthma and 20 matched children without asthma. Pulse oximetry was recorded on the first postoperative night. The mean early peak expiratory flow rate (PEFR) decreased in the asthmatics by 19.91 (95% confidence intervals (CI) 10.84–28.97)% and in the controls by 19.25 (10.70–27.80)%. The mean early FEV_1 decreased in the asthmatics by 16.02 (9.29–22.75)% and in the controls by 11.03 (2.86–19.19)%. The mean late decrease from baseline PEFR for the asthmatics was 18.55 (11.23–25.87)% but only 14.93 (7.89–21.97)% for the controls. The mean late FEV_1 was 8.2 (0.83–15.56)% below baseline in the asthmatics but only 6.82 (−0.79 to 14.42)% in the controls. There were no differences in overnight pulse oximetry. We conclude that healthy children exhibited a decrease in FEV_1 and PEFR after general anaesthesia for elective surgery, but this decline did not appear to be any greater in well controlled asthmatic children compared with children who did not have asthma. (*Br. J. Anaesth.* 1996; **77**: 200–202)

Key words

Asthma. Children. Anaesthesia, paediatric. Monitoring, spirometry. Lung, function.

There is a high prevalence of asthma in childhood; a recent study from Scotland showed a prevalence of greater than 14% [1]. With an increase in the range of surgical, investigative and therapeutic procedures requiring general anaesthesia, this suggests that many children with asthma are being exposed to general anaesthesia for both elective and emergency procedures. Inhalation agents have been shown to attenuate provoked increases in airways resistance and decreases in lung compliance in dogs [2] and in humans [3, 4], and have been used to treat acute bronchospasm [5, 6]. Animal studies have shown that neuromuscular blockers have variable effects on pulmonary resistance [7]. Opioids cause central respiratory depression, and some opioid drugs cause histamine-mediated bronchospasm. To our knowledge these effects have not been studied in children with asthma.

The aim of this study was to measure the effect of balanced general anaesthesia on respiratory function of children with asthma, compared with a group of children who did not have asthma. We also compared the patterns of postoperative overnight pulse oximetry in these two groups.

Patients and methods

The study was approved by the Research Ethics Committee of the Royal Liverpool Children's Hospital NHS Trust.

We studied all patients (the asthma group and controls) presenting for elective surgical procedures requiring general anaesthesia, aged 5–16 yr, and able to perform spirometry. All were free from intercurrent infection or respiratory illness at the time of study. In the asthma group, all children were previously diagnosed as having asthma, and were receiving prophylactic treatment with either inhaled sodium cromoglycate or inhaled corticosteroids.

The control group comprised 20 children, with no previous diagnosis of asthma. Children were excluded from the control group if they had a history of recurrent cough, wheeze or atopy.

Each asthmatic child was matched with a control for date of birth (within 1 yr), sex and type of operation (nose, throat or dental surgery, for example tonsillectomy, extraction of teeth; body surface or limb surgery, for example arthroscopy of the knee, removal of metalwork from limb; minor lower abdominal surgery, for example orchidopexy, herniotomy). Children undergoing major abdominal or cardiothoracic surgery were not studied. The technique of anaesthesia varied according to the operative procedure, however, each control child received an anaesthetic similar to that of the matched asthmatic child, including premedication, method of induction, volatile agent, airway management, neuromuscular block, method of ventilation and intraoperative analgesia. Postoperative analgesia was prescribed according to the type of surgery and size of the child, and administered on individual request. Regular medication was continued in the perioperative

period, but additional specific bronchodilator therapy was not prescribed, unless the clinical need arose.

The children were visited before operation, with a parent present, by one of the investigators, and written informed consent was obtained from the child (if appropriate), and parent.

Spirometry was performed during the preoperative visit using the portable Vitalograph Compact II (Vitalograph Ltd, Buckingham, UK). Values for peak expiratory flow rate (PEFR), forced expiratory volume in 1 s (FEV_1), forced vital capacity (FVC) and the ratio FEV_1/FVC, were obtained for each child after training in the correct technique. These were expressed as percentage of predicted values for height, age and sex [8]. This was repeated in the "early" postoperative period (sufficient recovery from anaesthesia to facilitate full effort at spirometry) and again in the "late" postoperative period (the following morning after 08:30 but before discharge). Spirometry measurements were carried out by one of three investigators (H.A.M., P.H.M. or H.C.R.), all of whom were trained in the lung function laboratory at the hospital.

On the first night after operation, pulse oximetry was recorded continuously for 8 h using the Ohmeda 3700e device (Ohmeda Ltd, Louisville, USA). The trend data from this monitor were downloaded onto a disk for analysis to produce a report of range, mean and frequency distribution of oxygen saturation. Of the 20 pairs studied, overnight pulse oximetry was completed only in 11 pairs.

Data were analysed by Wilcoxon signed ranks matched pairs test. Postoperative spirometry values were subtracted from baseline values and the size of the difference was analysed within each group. Paired comparisons of changes in lung function between asthmatics and controls were performed by subtracting the percentage decrease in FEV_1 or PEFR in the early or late postoperative period for each control from the percentage decrease in FEV_1 or PEFR at the same time for the asthmatic with whom they were matched. These differences were compared using the paired Student's *t* test.

Results

The asthmatic and control groups were comparable in age, weight, height and duration of operation. Preoperative PEFR and FEV_1 were also similar (table 1).

Table 1 Patient characteristics and preoperative PEFR and FEV, values in asthmatics and controls (mean (range))

	Asthmatics	Controls
Age (yr)	10.1 (6.5–15.1)	10.1 (5.5–16.0)
Height (cm)	136 (111–165)	140 (104–173)
Weight (kg)	34.9 (19.5–58.9)	36.8 (16.0–61.0)
Duration of operation (min)	38 (10–135)	46.6 (20–90)
Preop. PEFR (% predicted)	89.7 (60–115)	81.1 (70–117)
Preop. FEV_1 (% predicted)	88.3 (45–138)	85.0 (65–111)

In both groups there was a decrease in PEFR and FEV_1 in the early postoperative period, and in PEFR in the late postoperative period, which was greater than 10% and statistically significant. The decrease in FEV_1 in the late postoperative period was less than 10% in both groups, although this decrease did reach statistical significance in the asthmatics (table 2).

There was no significant difference between the groups in the decline in PEFR or FEV_1 at either postoperative time (data not shown).

Overnight pulse oximetry readings were similar for the asthmatics and controls in the 11 pairs studied. The mean difference in percentage oxygen saturation between asthmatics and controls was −0.03 (95% confidence interval −0.8 to 0.7) and the mean difference in time spent with oxygen saturations less than 90% was 0.87 (95% CI −0.1 to 1.9) h. These differences were not significant.

Discussion

To our knowledge this is the first study to investigate the overall effect of balanced general anaesthesia on lung function in children with asthma. We have demonstrated that healthy children, both asthmatics and non-asthmatics, undergoing general anaesthesia for elective surgery showed a decline in FEV_1 and PEFR in the early postoperative period. There was no difference in overnight oxygen saturation between the groups, and no clinical problems were observed in any patient.

Children with asthma are usually familiar with performing peak expiratory flow tests, and many have been taught how to perform spirometry tests. However, children who have never been suspected of having a respiratory disease will not have performed spirometry other than in this study. The control group had lower values for preoperative PEFR and FEV_1, and although these were not statistically significant, this may reflect a less practised technique. However, as measurements were recorded only after careful training had been completed, and consistent results were achieved for each child, this effect was minimized. We found no difference between the groups in preoperative baseline spirometry, which would indicate that the asthmatic children were well controlled with their current medication.

Both groups demonstrated the greatest decrease in PEFR and FEV_1 in the early postoperative period, when impaired co-operation secondary to results anaesthesia may have contributed to lower values. However, measurements were made only when it was considered that adequate consciousness had returned, and co-operation was similar to preoperative levels. The mean decreases in early postoperative PEFR and FEV_1 were greater than 10% in the asthmatics and controls and, as such, may be considered clinically and statistically significant. The decrease in FEV_1 in the late postoperative period was less than 10% in both groups. Although this late decrease in FEV_1 was statistically significant in the asthmatics, there was no statistically significant difference between asthmatics and controls, and it is

Table 2 Percentage decreases in PEFR and FEV_1 from baseline (mean (95% confidence intervals)). *P* values relate to significance of decreases from baseline

	Asthmatics	*P*	Controls	*P*
"Early" PEFR	19.9 (10.8–29.0)	0.001	19.3 (10.7–27.8)	0.04
"Early" FEV_1	16.0 (9.3–22.8)	0.0007	11.0 (2.9–19.2)	0.001
"Late" PEFR	18.6 (11.2–25.9)	0.0007	14.9 (7.9–22.0)	0.03
"Late" FEV_1	8.2 (0.8–15.6)	0.007	6.8 (−0.8 to 14.4)	0.12

unlikely to be clinically significant. The reduction in PEFR in the early postoperative period was accompanied by decreases of greater than 10% in FEV_1 (which is much less effort dependent than PEFR) [9] in the same period.

The small decreases in PEFR and FEV_1 were not associated with clinical problems and may represent small airways collapse caused by mucous plugging or bronchoconstriction. It is possible that in less well controlled asthmatics, with a preoperative deterioration in FEV_1, a similar decline in FEV_1 would cause clinical problems.

Statistical comparison of the differences between the groups for all decreases in PEFR and FEV_1 showed no significant differences at any time. With 20 pairs this study had a power of 0.7 to detect a difference of 10% in early FEV_1 between the asthmatics and controls. A study with a power of 0.9 to find a difference of 10% would require 33 pairs. In this large specialist paediatric centre, recruitment of 20 matched pairs took more than 2.5 yr and became increasingly difficult towards the end of the study because of the move towards day-stay surgery.

Overnight pulse oximetry did not differ between the groups. Fewer patients completed this part of the study because of equipment difficulties, failure of compliance during wakeful periods in the night and refusal by some children to sleep with the soft probe attached to a finger. Signal quality was frequently impaired in several cases by motion.

Ketamine and norketamine plasma concentrations after i.v., nasal and rectal administration in children†

J.-M. MALINOVSKY, F. SERVIN, A. COZIAN, J.-Y. LEPAGE AND M. PINAUD

Summary

It has been suggested that nasal administration of ketamine may be used to induce anaesthesia in paediatric patients. We have examined the pharmacokinetics of ketamine and norketamine after nasal administration compared with rectal and i.v. administration in young children. During halothane anaesthesia, 32 children, aged 2–9 yr, weight 10–30 kg, were allocated randomly to receive ketamine 3 mg kg^{-1} nasally (group IN3) or ketamine 9 mg kg^{-1} nasally (group IN9); ketamine 9 mg kg^{-1} rectally (group IR9); or ketamine 3 mg kg^{-1} i.v. (group IV3). Venous blood samples were obtained before and up to 360 min after administration of ketamine. Plasma concentrations of ketamine and norketamine were measured by gas liquid chromatography. Statistical comparisons were performed using ANOVA and the Kruskall–Wallis test, with $P < 0.05$ as significant. Mean plasma concentrations of ketamine peaked at 496 ng ml^{-1} in group IN3 within 20 min, 2104 ng ml^{-1} in group IN9 within 21 min, and 632 ng ml^{-1} in group IR9 within 42 min. Plasma concentrations of norketamine peaked at approximately 120 min after nasal ketamine, but appeared more rapidly after rectal administration of ketamine and were always higher than ketamine concentrations in the same situation. Calculated bioavailability was 0.50 in groups IN3 and IN9 and 0.25 in group IR9. We conclude that nasal administration of low doses of ketamine produced plasma concentrations associated with analgesia, but using high doses via the nasal route produced high plasma concentrations of ketamine similar to those that induce anaesthesia. However, the large volume of ketamine required was partly swallowed and led to an unacceptable variability of effect that precludes this route for induction of anaesthesia. (*Br. J. Anaesth.* 1996; **77**: 203–207)

Key words

Anaesthesia, paediatrics. Anaesthetic techniques, i.v. Anaesthetic techniques, rectal. Anaesthetic techniques, nasal. Pharmacokinetics, ketamine. Premedication, ketamine. Anaesthetics i.v., ketamine.

Although psychic emergence phenomena from ketamine anaesthesia restrict its use in paediatric patients [1], it may be used with premedication (i.e. midazolam) which prevents these phenomena [2] when administered first. The original agent remains popular for induction of anaesthesia in young children as it can be given as the sole anaesthetic agent and by alternative non-invasive routes such as rectally [3, 4].

Previous studies have reported its use by the oral and nasal routes. After oral ketamine 6 mg kg^{-1}, approximately 25 % of a paediatric population appeared asleep or barely arousable within 10 min [5]. The nasal route has been investigated for midazolam [6] or opioid [7] premedication and it has been tested with ketamine as an adjunct for induction of anaesthesia [8]. Loss of responsiveness occurred within 3–10 min in 35 % of children after one to three 3-mg kg^{-1} nasal ketamine doses [8]. This suggests that nasal administration of ketamine might be used for induction of anaesthesia.

Ketamine pharmacokinetics have been described after i.v. [9], i.m. [10], oral [10] and rectal [4] administration, but not after nasal administration. In this study we have determined and compared the pharmacokinetics of ketamine and its main metabolite, norketamine, when administered by nasal, rectal and i.v. routes in healthy anaesthetized children.

Patients and methods

After obtaining institutional approval and written informed consent from parents, we studied 32 ASA I boys, 2–9 yr of age, weighing 10–30 kg, undergoing minor urological surgery. Exclusion criterion included: rhinopharyngitis, digestive disorders, treatment with theophylline, H_2 receptor antagonists, β-lactamines associated with clavulanic acid and aminoglycosides, and an anaesthetic procedure involving barbiturate administration.

Anaesthesia was induced with halothane (2 MAC) and 50 % nitrous oxide in oxygen via a face mask. Anaesthesia was maintained with halothane for induction of anaesthesia (1 MAC and during ketamine administration) without tracheal intu-

bation. After cannulation of a vein on the forearm using a short 20-gauge catheter and i.v. injection of atropine 15 μg kg^{-1}, children were allocated randomly to one of four groups to receive 5% ketamine (Parke Davis Lab.) as follows: group IN3 ($n = 8$) received ketamine 3 mg kg^{-1} nasally; group IN9 ($n = 8$) ketamine 9 mg kg^{-1} nasally; group IV3 ($n = 8$) ketamine 3 mg kg^{-1} i.v.; and group IR9 ($n = 8$) ketamine 9 mg kg^{-1} rectally. In groups IN, half of the indicated dose was administered in each nostril within 15 s. All children received an enema 1 h before anaesthesia and rectal administration was performed via a short air-washed cannula. After i.v. administration, the venous catheter was flushed with physiological saline 10 ml. In all groups, heart rate and pulse oximetry were monitored continuously, and non-invasive arterial pressure and ventilatory frequency recorded at regular intervals during anaesthesia. Administration of halothane was stopped 15 min after administration of ketamine in all children. Time elapsed between ketamine administration and complete recovery from anaesthesia (when the child was able to open his eyes and answer correctly to verbal command) was recorded. Doses and time of analgesic requests during the postoperative period were noted.

Thirteen 5-ml venous blood samples were obtained before and 5, 10, 15, 20, 30, 45, 60, 120, 180, 240, 300 and 360 min after administration of ketamine. Plasma was separated by centrifugation and stored at −20 °C until analysis. Plasma concentrations of ketamine and its major metabolite, norketamine, were measured by gas–liquid chromatography (supplied by Parke-Davis-France). The internal standard was diphenhydramine 5 μg ml^{-1}. The calibration curves for ketamine and norketamine were linear within the range 0–2000 ng ml^{-1}. Greater concentrations required dilution of plasma samples before extraction. The standard variations for ketamine and norketamine were, respectively, 4.4% and 6.9% for 20 ng ml^{-1}, and 1.7% and 3.4% for 2000 ng ml^{-1}.

Pharmacokinetic variables were calculated by conventional means from plasma concentration–*vs*–time data. Ketamine and norketamine concentration–*vs*–time curves obtained for individual patients were fitted to the sum of exponential functions derived from Colburn [11] and interpreted as one- or two-compartment models. Pharmacokinetic data were fitted using the Siphar program [12], with a weighing function of $1/y^2$. The quality of fit of the two-compartment model was assessed by the presence of a random scatter of data around a calculated value [13], and by visual assessment of the residuals of the observed values from the fitted curve. After modelling, the rate constant for elimination (k_e) was obtained, and the elimination half-life ($T_{1/2}$) was calculated as (0.693 k_e). The area under the plasma concentration curve from 5 to 360 min (AUC$_{5-360}$) was calculated by the trapezoidal rule and was extrapolated from the origin to infinity (AUC$_{0-\infty}$) from the k_{abs} and k_n slopes. Clearance was calculated using the formula: Cl = dose/AUC. Analysis from the extrapolated area allowed estimation of steady state volume of distribution (V^{ss}). Availability (F) for the different routes was calculated after children were paired between each non-i.v. group and group IV according to weight. In each non-i.v. group, peak ketamine concentration and its time were estimated from the fitted model. Statistical comparisons were carried out using ANOVA and the Kruskall–Wallis test where appropriate; $P < 0.05$ was considered significant. Data are presented as mean (SD).

Results

Mean age and weight of the children were, respectively, 4.8 (range 2–8) yr and 18.6 (SD 2.9) kg in group IV3; 4.8 (3–9) yr and 18.4 (4.7) kg in group IN3; 3.3 (2–7) yr and 17.1 (14.9) kg in group IN9; and 4.0 (3–9) yr and 17.8 (5.7) kg in group IR9 (ns). Surgical procedures included herniorrhaphy, repair of undescended testis, circumcision or hypospadias

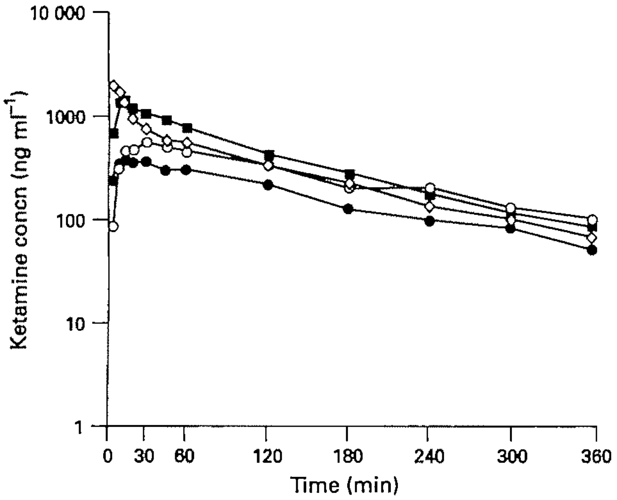

Figure 2 Logarithmic conversion of mean ketamine plasma concentration–*vs*–time curves in group IV3 (◇), group IN3 (●), group IN9 (■) and group IR9 (○).

repair. No children experienced coughing or defaecation, nasal disturbances or rectal postoperative lesions after intranasal or rectal administration of ketamine.

Mean arterial pressure and heart rate did not vary significantly from baseline values in any group during halothane anaesthesia or ketamine administration. Sp_{O_2} did not decrease except in two children who received i.v. ketamine and demonstrated a transient decrease at 88% and 89% from baseline values of 98%; these children had plasma ketamine concentrations greater than 2000 ng ml^{-1} at 5 and 10 min after administration of ketamine. Assisted ventilation via a face mask was used temporarily (less than 5 min) in these patients. Ventilatory frequency did not vary in groups IN3 and IR9, but increased significantly at 5 min in group IV3 and at 10 min in group IN9 (+34 (12)% and 46 (21)%, respectively). No additional analgesia was required in any group during surgery or during the 6 h after operation. Complete recovery from anaesthesia was delayed in group IN9 (107 (23) min) compared with the other groups: group IN3, 72 (15) min; group IR9, 57 (11) min; and group IV3, 63 (16) min ($P < 0.01$).

Because of blood sampling difficulties, two children were excluded from pharmacokinetic analysis (one in group IN9 and another in group IR9). Mean ketamine and norketamine plasma concentration–*vs*–time curves for each group are shown in figure 1. Logarithmic conversion of mean plasma concentration–*vs*–time curves for ketamine in each group are presented in figure 2. Individual $C_p$max and tC_pmax values for ketamine in the different groups are shown in table 1. Pharmacokinetic variables are summarized in table 2. After pairing children according to weight and age, estimated bioavailabilities were, respectively, 0.50 (0.19) after nasal ketamine 3 mg kg^{-1} and 0.50 (0.27) after 9 mg kg^{-1}, and 0.25 (0.19) after ketamine 9 mg kg^{-1} rectally.

Discussion

We have found that the same dose of ketamine (9 mg kg^{-1}) induced more rapid and greater plasma concentrations after nasal than after rectal administration, but that the rectal route was associated with earlier appearance of norketamine because of first-pass metabolism.

The doses used in our study were those that induced general anaesthesia by the i.v. and rectal

routes, and for the nasal route were those reported as effective in a previous study [8]. However, a relationship with clinical effects may not be established as sampling occurred during general anaesthesia. Moreover, it may be noted that the volumes administered nasally in group IN9 were large and probably unacceptable in a conscious, unpremedicated child.

There are several problems in the pharmacokinetic interpretation of the data obtained after different models of administration of ketamine as children were not their own controls. However, such comparisons between non-i.v. and i.v. administrations of anaesthetic agents are frequently made in children who are not their own controls [14–16]. Therefore, in order to obtain a meaningful analysis, children were paired accordingly to age and weight between non-i.v. and i.v. groups for estimation of ketamine bioavailability. Furthermore, to facilitate venous access and blood sampling, ketamine was administered during general anaesthesia to ensure maintenance of anaesthesia and postoperative analgesia as a result of generation of norketamine which is a potent analgesic drug [10]. Such a study design is seldom used but ketamine associated with propofol has been proposed for ambulatory surgery [17]. Our study did not allow pharmacokinetic analysis of norketamine because the sampling period could not be extended further than 6 h in those children treated on a day-case hospital stay basis.

Ketamine metabolism is dependent on hepatic blood flow and could therefore be influenced by co-administered drugs, for example halothane. Halothane induces a marked decrease in hepatic blood flow, reduces intrinsic drug metabolism capacity [18] and diminishes ketamine clearance [19]. Its use could therefore enhance ketamine plasma concentrations and delay norketamine generation. However, all children exhibited a similar haemodynamic state when they received the same dose of halothane, and therefore the influence of halothane on hepatic blood flow was probably the same in all children.

The pharmacokinetic variables after i.v. ketamine were similar to those reported previously in adult patients or children [9, 20–24] and are summarized in table 3. The volume of distribution of approximately 3 litre kg^{-1} reflects the high liposolubility of ketamine and a high clearance (22 ml kg^{-1} min^{-1}) accounts for the relatively short elimination half-life. As described previously the appearance of norketamine was delayed which suggests that norketamine plays a role in the clinical duration of action of ketamine. In all children, plasma concentrations of norketamine 6 h after administration of i.v. ketamine were greater than 150 ng ml^{-1}, the threshold for analgesia reported previously [10].

The amount of ketamine which reached the systemic circulation was reduced with the non-i.v. routes. The bioavailability of ketamine in the absence of a first-pass hepatic effect, as observed via the nasal route, was approximately twice that observed via the rectal route. Certainly, ketamine administration during general anaesthesia leads to maximal mucosal absorption of the drug, proportional to the dose administered, with an early plasma peak in both nasal groups. Plasma ketamine concentrations in group IN9 were consistent most of the time with those associated with induction of anaesthesia. However, general anaesthesia and the supine position avoided expulsion of part of the dose from sneezing or coughing, or swallowing; however, two children receiving a large volume in group IN9 exhibited plasma concentration decay curves consistent with digestive absorption of the drug. Nevertheless, the amount of drug required with the current formulation of ketamine implies that intranasal administration of a large volume of solution which would probably be swallowed by a conscious child would be even more than that observed in this study. This leads to an unacceptable variability of effect which precludes the use of this route for induction of anaesthesia.

After rectal administration, ketamine absorption was delayed and interindividual variations were large. Despite the fact that every child in this group received a rectal enema before induction of anaesthesia, rectal evacuation was never certain, and the differences in rectal pH values of children [24] might modify drug absorption. As described previously [4], norketamine generation was rapid in this group, because of first-pass metabolism. These early high plasma norketamine concentrations may participate in the anaesthetic action of ketamine in this situation, and partly compensate for low bioavailability. This low bioavailability is similar to that described after oral administration of ketamine [9].

Determinants of duration of ICU stay after coronary artery bypass graft surgery

A. Michalopoulos, G. Tzelepis, G. Pavlides, J. Kriaras, U. Dafni
and S. Geroulanos

Summary

Prediction of duration of a patient's stay in the ICU after cardiac surgery is difficult. In 652 consecutive adult patients undergoing elective coronary artery bypass graft (CABG) surgery, we analysed prospectively preoperative and immediate postoperative variables thought to influence duration of stay in the ICU. With univariate analysis, we found that age, preoperative left ventricular ejection fraction, bypass time, aortic cross-clamp time, blood transfusions and the number of inotropic agents administered in the immediate postoperative period (for at least 6 h) were significant correlates of duration of stay in the ICU. However, logistic regression analysis showed that the number of inotropes was the most important determinant of stay in the ICU, with an overall prediction accuracy of 94.8%. The main cause of prolonged stay in the ICU (more than 2 days) was low cardiac output syndrome. We conclude that analysis of perioperative variables enhanced our ability to accurately predict duration of stay in the ICU in cardiac surgery patients. The number of inotropic agents administered during the first 6 h after operation was the most important determinant of duration of stay in the ICU. (*Br. J. Anaesth.* 1996; 77: 208–212)

Key words
Surgery, cardiovascular. Intensive care. Heart, coronary artery bypass. Risk.

Despite recent efforts to bypass intensive care unit (ICU) stay [1], cardiac surgery patients are invariably monitored in the ICU for a period of time that varies from 1 to several days. Prolonged stay in the ICU not only increases the overall costs of cardiac surgery, but it may also limit the number of operations performed. Therefore, the ability to accurately predict the duration of stay in the ICU and patient outcome is important.

The scoring systems used to predict a patient's stay in a general ICU have not been found to be useful in the postoperative cardiac ICU [2, 3]. Over the past few years, attempts have been made to develop predictive models of stay in the ICU with special applicability to cardiac surgery patients. However, the majority of reported models are complex, impractical for intercentre use and of modest predictive ability [4–6]. This may result partly from the fact that all studies analysed preoperative variables and ignored variables related to the operation itself.

In this study, we have assessed determinants of length of stay in the ICU in postoperative coronary artery bypass graft (CABG) surgery patients by analysing both preoperative and immediate postoperative variables. This approach has enabled us to develop a simple and more accurate predictive index of stay in the ICU.

Patients and methods

From January 1994 to December 1994, we studied prospectively 652 consecutive patients undergoing elective CABG surgery in our hospital. We recorded patients variables, New York Heart Association (NYHA) class and preoperative left ventricular ejection fraction assessed by angiography (grade 1 > 50%; grade 2 35–50%; grade 3 20–34%; and grade 4 < 20%).

We also recorded the type of cardioplegia used, number of grafts, aortic cross-clamp time and bypass time. In addition, we recorded the number of inotropic drugs administered during the first 6 h in the ICU. Collection of these data in no way interfered with or affected the care of patients being studied; therefore, it was deemed that patient consent was not required. Approval for this study was obtained from the Ethics and Research Committee for our institution.

Inotropic drugs were used to treat low cardiac output syndrome, defined as a cardiac index < 2 litre min^{-1} m^{-2}, despite optimal filling pressures (wedge pressure 12 mm Hg). Inotropes were included only if they were given in the ICU for at least 6 h, immediately after surgery. In this situation, dobutamine, adrenaline or dopamine, up to maximum doses (adrenaline 2 μg kg^{-1} min^{-1}, dobutamine 20 μg kg^{-1} min^{-1} or dopamine 20 μg kg^{-1} min^{-1}) were

Class II	205	31.4
Class III	130	19.9
Class IV	96	14.7

usually used initially. If there was need for additional inotropic support (persistence of condition) within this critical period, milrinone or noradrenaline ($1\ \mu g\ kg^{-1}\ min^{-1}$ or $0.3\ \mu g\ kg^{-1}\ min^{-1}$, respectively) were then added [7]. Dopamine at renal doses was excluded. The amount of blood transfused in the operating room and during the first 6 h after operation was also recorded. Blood transfusion was given when the patient's packed cell volume (PCV) was < 27%.

Duration of mechanical ventilation, all postoperative complications, duration of stay in the ICU and patient outcome were recorded for all patients. For this analysis, prolonged stay in the ICU was defined as greater than 2 days. No patient was excluded. Patient outcome was evaluated on the day of ICU discharge.

Data were analysed using BMDP statistical software (Los Angeles, CA, USA) [8]. Continuous variables were analysed using the two-sample *t* test. The chi-square test was used for discrete variables. To assess the ability of independent variables to predict a dependent variable, the odds ratio was calculated [9]. Furthermore, the data were subjected to logistic regression analysis where ICU duration constituted the binary dependent variable (2 *vs* > 2 days). Sex and cardioplegia (crystalloid *vs* blood) were categorical predictors, and ejection fraction, aortic cross-clamp time, bypass time, number of grafts, units of blood transfused and number of inotropic drugs administered were interval-scaled predictors. The fit of the model was assessed by the Hosmer–Lemeshow goodness-of-fit statistic [10]. Data are reported as the mean (SD) and were considered significant when $P < 0.05$.

Results

Patient characteristics and preoperative data are shown in table 1. For all patients, mean duration of stay in the ICU was 2.3 (SD 1.6) days (range 0.75–62 days) and duration of mechanical ventilation 0.8 (0.3) days. Of all patients, 585 patients (89.7%) were discharged in less than 2 days (group A), whereas 67 patients (10.3%) remained in the ICU for more than 2 days (group B). Patient characteristics and differences in perioperative variables for both groups are presented in table 2. The two groups did not differ in sex distribution, cardioplegia, preoperative haemoglobin (PCV) or number of grafts. Ejection fraction was a significant predictor of prolonged stay in the ICU ($P < 0.001$). Use of inotropes was also associated with prolonged stay in the ICU. For example, use of one inotrope was associated with an odds ratio of 2, and use of two inotropes with an odds ratio of 104 ($P < 0.0001$). Aortic cross-clamp time in excess of 90 min was associated with a statistically significant and sharp increase in odds ratio for prolonged stay in the ICU ($P < 0.001$). Bypass time longer than 120 min increased the risk for prolonged stay in the ICU, corresponding to an odds ratio of 4.3 ($P < 0.001$). There was a non-monotonic relation of risk for prolonged stay in the ICU and the amount of blood transfused; patients who received more than 6 u. of blood were at a substantially increased risk for prolonged stay in the ICU (odds ratio 13.5; $P < 0.001$).

Table 3 shows the results of a forward stepwise selection of variables into the logistic model. Five variables were entered based on their statistical significance (entering criterion $P < 0.15$). A backward selection procedure led to the same set of five variables in the model (removing criterion $P > 0.20$). The great majority of improvement in this model fit

Table 4 Number of patients (%) in ICU groups as a function of number of inotropes used

	Inotropes			
	0	1	2	3
≤ 2 days	418 (98.3)	147 (96.7)	19 (31.1)	1 (7.1)
> 2 days	7 (1.7)	5 (3.3)	42 (68.9)	13 (92.9)
Total	425 (100)	152 (100)	61 (100)	14 (100)

Table 5 Number of patients (%) in ICU groups as a function of inotrope groups used

	Inotropes		
	0 or 1	≥ 2	Total
≤ 2 days	564 (96.4)	21 (3.6)	585 (100)
> 2 days	13 (19.4)	54 (80.6)	67 (100)

was associated with the number of inotropes used, the number of blood units and preoperative ejection fraction.

Table 4 shows the number and percentage of patients in each ICU stay-group for the four levels of inotropes observed. Using inotropes as a binary predictor, with values of 0 and 1 indicating stay in the ICU of 2 days or less, and 2 or more indicating more than 2 days, the overall prediction accuracy was 95.1 % (620 of 652) based on 96.6 % for predicting short stays (565 of 585) and 82.1 % for long stays (55 of 67) (table 5). These rates are close to the five predictor model of table 3 and also to a five predictor model where the binary inotropes variable itself was substituted for the interval variable. Thus the binary inotropes variable is an accurate and simple predictor of stay in the ICU.

The causes resulting in prolonged stay in the ICU were low cardiac output syndrome in 35 (52.2 %), respiratory failure in eight (11.9 %), neuro-psychiatric abnormalities in five (7.5 %) and combination of the above in 19 (28.3 %) patients. For both groups, mean duration of mechanical ventilation, ICU and hospital stay, and mortality rate are presented in table 6. The overall ICU mortality rate was 0.8 %.

Causes for a longer stay in the ICU for the group receiving less than two inotropes ($n = 13$) were hypoxaemia ($n = 6$), atrial fibrillation ($n = 3$), their combination ($n = 3$) and mental disturbances ($n = 1$).

Discussion

This study included both preoperative and immediate postoperative variables in a logistic regression model and developed an index to predict duration of stay in the ICU after cardiac surgery. We found that patients who had a low ejection fraction, had received a large number of units of blood or more than one inotropic agent remained in the ICU for a longer period than usual. Sex, bypass time, aortic cross-clamp time and number of grafts were not significant predictors. Among all variables examined, the number of inotropic drugs administered in the immediate postoperative period was the most reliable predictor of stay in the ICU, with an overall predictive accuracy of 94.8 %. This is supported by our finding that the most frequent cause of prolonged stay in the ICU was low cardiac output syndrome; however, it should be noted that the number of inotropes rather than inotrope use was the significant factor.

The major limitation of this study was that this index was derived after the patient's stay in the ICU for 6 h. In this sense, it cannot be used as a preoperative prognostic indicator of duration of stay in the ICU. In our study, there was a delay of a few hours for predicting the duration of stay in the ICU, but we believe that there is still considerable value in predicting the length of stay in the intensive care unit in the early postoperative period. The accuracy

Table 6 Duration of mechanical ventilatory support, ICU and hospital stay, and mortality rate for both groups (mean (SD))

	Group A (ICU stay ≤ 2 days)	Group B (ICU stay > 2 days)	*P*
Mech. ventilation (days)	0.5 (0.05)	3.8 (1.4)	0.001
ICU stay (days)	1.3 (0.3)	7 (4.5)	0.001
Hospital stay (days)	7.1 (0.8)	14.6 (3.9)	0.001
ICU mortality	0.3 %	4.5 %	0.0001

of our prediction was much higher compared with similar, previous studies which used only preoperative variables. The determinants of this study can be considered similar to the APACHE II scoring system, which predicts patient outcome at the time of admission to the ICU, but has a poor performance in cardiac surgery patients [11].

Over the past 5 yr, several studies have developed predictive indices of stay in the ICU after cardiac surgery. The majority of these studies have included preoperative variables and, in general, have not taken into account events that affect patient outcome during the operative or immediate postoperative period. A great disparity in type and number of independent variables analysed has been reported. Tuman and co-workers [4] found 11 variables to be significantly associated with stay in the ICU, including emergency surgery, age, preoperative renal dysfunction, previous myocardial infarction, cerebrovascular disease, type of surgery, congestive heart failure and left ventricular dysfunction. Although the duration of stay in the ICU in this study correlated with a clinical risk score derived from these variables, no accurate predictive index of stay in the ICU based on clinical score was provided. Furthermore, it cannot be determined which risk factor is the most significant predictor of length of stay in the ICU.

In a similar study of preoperative variables, Tu and co-workers [12] suggested that length of stay in the ICU after cardiac surgery could be predicted by a multivariate predictive index. Five variables were found to be statistically significant independent predictors for a prolonged stay in the ICU (age, female sex, left ventricular function, urgency of surgery and type of surgery). A predictive index was developed for length of stay in the ICU with a risk score of 0–12. Patients with a low risk score remained in the ICU for a few days, while patients with a high risk score had a prolonged stay in the ICU. However, this model has a poor predictive ability; 31.7% of patients with a low risk score (0–3) stayed more than 2 days stay in the ICU, whereas only 69.4% of patients with a high risk score (> 8) had a prolonged (> 2 days) stay in the ICU. The authors acknowledged that length of stay in the ICU can never be predicted with certainty.

One year later, Tu, Jaglal and Naylor [13] reported that duration of stay in the ICU after cardiac surgery could be predicted using a six-variable risk index which included age, sex, preoperative ejection fraction, type of surgery, urgency of surgery and reoperation. Although the authors considered prolonged stay in the ICU as longer than 6 days, the overall predictive ability of their index was poor (67%).

The fundamental difference between our study and those described above is that we took into account not only preoperative variables, but also significant variables related to both the operative and immediate postoperative period, such as number of inotropes administered and blood transfusions. We found that duration of stay in the ICU depended predominantly on a single critical variable, number of inotropes administered during the immediate postoperative period. This is not surprising because inotropic support reflects poor cardiac function. It follows that the group requiring intensive inotropic support would include patients with intraoperative complications (e.g. myocardial ischaemia or infarction), inadequate revascularization, low cardiac output syndrome related to systemic inflammatory response syndrome (SIRS), stunned myocardium or inadequate myocardial protection during bypass. Apparently, none of these conditions can be predicted accurately by any preoperative variable. On the other hand, in some high-risk cases (e.g. low ejection fraction) there may be great improvement in left ventricular function after operation as a result of successful revascularization. This is supported by the study of Zaroff and colleagues who found that, although low preoperative ejection fraction is a known predictor of poor immediate postoperative outcome after cardiac surgery, not all patients with low preoperative ejection fraction required inotropic support [14]. In both cases, the models based on preoperative variables are likely to fail in predicting stay in the ICU.

Our findings are in agreement with those reported by Weintraub and co-workers [15], who showed that the correlates of prolonged hospital stay could not be predicted by preoperative variables alone. The authors emphasized that serious complications were responsible for prolonging the length of stay after coronary artery bypass grafting surgery.

Comparison of propofol and a propofol–methohexitone mixture for induction of day-case anaesthesia

N. THOMPSON AND G. S. ROBERTSON

Summary

We studied 99 patients undergoing day-case urological surgery, allocated randomly to receive a sleep dose of either 1% propofol or a mixture of equal volumes of 1% propofol and 0.5% methohexitone, and thereafter a standardized anaesthetic. With the exception of minor differences in intraoperative heart rate there were no significant differences between the two groups in induction properties and complications, intraoperative variables, rate of recovery or postoperative sequelae. (*Br. J. Anaesth.* 1996; **77**: 213–216)

Key words

Anaesthesia, day-case. Anaesthetics i.v., propofol. Anaesthetics i.v., methohexitone. Anaesthetic techniques, induction.

Anaesthesia for day-case surgery is designed to provide rapid, uncomplicated recovery and discharge from hospital within a few hours of surgery. Although methohexitone has previously been used commonly, propofol is now considered the induction agent of choice for day-case anaesthesia because of its short recovery time and low incidence of postoperative sequelae [1]. However, compared with methohexitone, propofol produces a greater degree of cardiovascular and respiratory depression [2] and is more expensive. A combination of these two agents might accentuate their individual advantages, while minimizing the side effects. In this study, we have compared the properties of a mixture of propofol and methohexitone with those of propofol alone for day-case anaesthesia.

Patients and methods

After approval of the local Ethics Committee, we studied 99 patients undergoing day-case urological surgery; all gave informed consent and were ASA grade I or II, aged 16–70 yr. Exclusion criteria included specific contraindications to the study drugs or halothane anaesthesia.

After recording of baseline heart rate, systolic, diastolic and mean arterial pressures (MAP), and Sp_{O_2}, a suitable vein was cannulated. Patients were then allocated randomly to one of two groups, and each patient received a sleep dose of induction agent, with the end-point defined as loss of verbal contact. For patients in group A the syringe contained 9.5 ml each of methohexitone 5 mg ml^{-1} in 0.9% sodium chloride and propofol 10 mg ml^{-1}, with 2% lignocaine 1 ml. For those in group B the syringe contained 19 ml of propofol 10 mg ml^{-1} with 2% lignocaine 1 ml. Neither investigator was aware of the patient's group, and it was not possible to differentiate visually between the contents of the syringes. All inductions and subsequent anaesthetics were carried out by one investigator (G.S.R.). The volume of agent needed to induce anaesthesia was noted, and also pain on injection, laryngeal spasm, cough, hiccup or apnoea. The duration of apnoea was noted, and the lungs ventilated manually if it was longer than 20 s or if Sp_{O_2} decreased to less than 90%.

Anaesthesia was maintained with halothane and 60% nitrous oxide in oxygen. Heart rate, MAP and Sp_{O_2} were recorded every minute for the first 10 min of anaesthesia. At the end of surgery the halothane concentration was reduced to 0.5% for 3 min. Halothane and nitrous oxide were then discontinued, and the duration of halothane administration was noted.

During the recovery period, all patients received oxygen 4 litre min^{-1} via a Hudson mask. MAP, heart rate and Sp_{O_2} were recorded at 1-min intervals. Recovery scoring was conducted at 1-min intervals by one investigator (N.T.) using a scoring system validated in a previous study (appendix) [3]. Complications including nausea, vomiting, cough, hiccup or laryngeal spasm during the recovery period were recorded. Patients were transferred from the recovery area to the day ward, where any later complications were noted.

STATISTICAL ANALYSIS

Data were analysed using Student's *t* test, the chi-square test and Fisher's exact test, where appropriate. To analyse the recovery profiles, test statistics were constructed using general estimating equations, which were then used to fit a marginal proportional odds model [4].

Results

There were no significant differences ($P < 0.05$) between the two groups in age, sex, preoperative cardiovascular variables or duration of anaesthesia (table 1). For group A (propofol–methohexitone) the

mean volume of induction agent was 17.5 ml (range 12–20 ml) and for group B (propofol) 17 (11–20) ml. One patient in the propofol–methohexitone group exhibited marked spontaneous movement on induction. There were no significant differences in the occurrence of pain on injection, cough, laryngeal spasm, hiccup and apnoea on induction between the groups (table 2).

Heart rate, MAP and Sp_{O_2} were compared between the two groups for each of the first 10 min of anaesthesia. Heart rate was consistently higher in group A, but the difference was significant only at 1, 4, 9 and 10 min (fig. 1). There were no other significant differences in these variables between the two groups at any time during anaesthesia or recovery. One patient in each group exhibited runs of ventricular ectopics during operation, which in both cases were treated successfully with i.v. lignocaine. One patient in the propofol group required atropine 0.3 mg i.v., after 5 min of anaesthesia to treat a bradycardia of 43 beat min^{-1}.

Mean time to full recovery was similar in both groups (group A, 7 (SD 3.7) min, group B, (6.7 (3.1) min; ns). Comparison of the changes with time of the various elements of the recovery scores was made using a marginal proportional odds model. This revealed no difference in the time profiles of recovery between the two groups. There was no significant difference in complication rates during recovery (table 3).

Discussion

In day-case anaesthesia, propofol is the "gold-standard" by which other induction agents are judged. However, its superior recovery profile [2, 5, 6] and relative infrequency of postoperative complications [1, 5, 7] are offset by its tendency to cause apnoea on induction [2, 5] and greater cardiovascular instability than other induction agents [2, 5, 6].

Although specific information on the compatibility and stability of mixtures of propofol and methohexitone is not available, the data sheets on the use of these drugs did not suggest any obvious risk of physical or chemical incompatibility. It is recommended that, because of differences in pH, solutions of methohexitone should not be mixed with acid solutions. As the pH of propofol is 7.5, and that of the propofol—methohexitone mixture 8.9 [personal observation], physical incompatibility would be unlikely. The remarkably similar mean volumes of the induction agents (17.5 ml and 17 ml) provides further circumstantial evidence that no significant pharmacological interaction or change in drug potency took place in the drug mixture. The 1:2

Table 4 Comparison of properties of propofol and propofol–methohexitone in this study with properties of propofol and of methohexitone described in previous studies (all values are given as percentages)

	Propofol (this study)	Propofol–methohexitone (this study)	Propofol (previous studies)	Methohexitone (previous studies)
Pain on injection	4	6	0–48 [1,2,6,9,10,12]	4–56 [2,6,9,10,13]
Cough	8	11	12 [2]	32 [2]
Laryngeal spasm	0	0	—	12 [2]
Hiccup	4	0	0–5 [2,6,9]	24–40 [2,6,9]
Spontaneous movement	0	2	0–10 [2,6,9]	0–24 [2,6,9]
Apnoea	65	53	12–60 [2,5,10]	14–36 [2,10,11]
Postoperative nausea and vomiting	0	0	1.9–20 [2,6,7,9]	20–40 [2,6,11]

dilution of propofol in this study is well within the recommended maximum dilution of 1:5 using solutions such as 5% glucose, and a previous study using mixtures of propofol and alfentanil did not cause any pharmacodynamic or physical instability [8]. For the purposes of this study, in view of the recommendation that dilutions of propofol should be used within 6 h, mixtures made more than 2 h previously were discarded. No visible layering, separation or development of particles occurred at any time in the drug mixtures.

In this study, the behaviour of the propofol–methohexitone mixture was indistinguishable clinically from that of propofol alone during induction, maintenance and recovery. While the propofol–methohexitone group maintained a slightly higher heart rate during the first 10 min of anaesthesia (fig. 1), clinically this was not noticeable or significant. Changes in MAP were similar in both groups (fig. 1), although it might have been anticipated that the drug mixture would have caused less reduction in MAP because of the lesser hypotensive effect of methohexitone [2, 5, 6, 10].

Compared with the results of previous studies (table 4), the propofol–methohexitone mixture compared favourably with methohexitone alone in all aspects except the incidence of apnoea on induction, which was higher with the drug combination, presumably reflecting the addition of propofol. In this study both groups had a lower incidence of pain on injection (because of the addition of lignocaine [12, 13]), and of postoperative nausea and vomiting than described previously.

At present in the UK propofol costs £4.42 for a 200-mg ampoule. Methohexitone costs 41p for a 50-mg dose from a 500-mg ampoule mixed to 0.5% strength with water or saline; 20 ml of a 50:50 propofol–methohexitone mixture would therefore cost £2.62, a cost saving of £1.80 per patient compared with propofol. In a day-case unit treating 5000 patients per annum, this would represent an annual saving of approximately £9000 at current prices. The inconvenience of mixing methohexitone and preparing syringes was found by the authors to be negligible.

ASA classification and perioperative variables as predictors of postoperative outcome

U. WOLTERS, T. WOLF, H. STÜTZER AND T. SCHRÖDER

Summary

In a prospective study of 6301 surgical patients in a university hospital, we examined the strength of association between ASA physical status classification and perioperative risk factors, and postoperative outcome, using both univariate analysis and calculation of the odds ratio of the risk of developing a postoperative complication by means of a logistic regression model. Univariate analysis showed a significant correlation ($P < 0.05$) between ASA class and perioperative variables (intraoperative blood loss, duration of postoperative ventilation and duration of intensive care stay), postoperative complications and mortality rate. Univariate analysis of individual preoperative risk factors demonstrated their importance in the development of postoperative complications in the related organ systems. Estimating the increased risk odds ratio for single variables, we found that the risk of complication was influenced mainly by ASA class IV (risk odds ratio = 4.2) and ASA class III (risk odds ratio = 2.2). We conclude that ASA physical status classification was a predictor of postoperative outcome. (*Br. J. Anaesth.* 1996; **77**; 217–222).

The American Society of Anesthesiologists' (ASA) classification of physical status was introduced in 1941 by Saklad [1] in an attempt to provide a basis for comparison of statistical data in anaesthesia. The classification was revised in 1963 [2] with the number of classes being reduced from seven to five. Several retrospective studies have demonstrated a correlation between ASA classification and perioperative mortality [3–8], and have suggested its usefulness as a predictor of patient outcome. Prospective studies correlating ASA classification with both perioperative mortality and morbidity have suffered either from small patient numbers [4] or from focusing only on anaesthetic complications [9, 10].

The aim of this prospective study was to evaluate the prognostic value of ASA classification with regard to perioperative variables such as blood loss, duration of intensive care stay, postoperative complications and mortality. In addition, we investigated the relationship between the presence of specific preoperative disease states (arterial hypertension, previous myocardial infarction, smoking and severe bronchopulmonary disease) and the development of major postoperative complications (cardiac and pulmonary), and the need for postoperative ventilation. Further, we used logistic regression analysis to provide an estimate of the risk odds ratio implied by specific perioperative variables, together with an estimate of the risk odds ratio when more than one perioperative variable was considered.

Patients and methods

All patients operated on in the Department of General and Vascular Surgery, University of Cologne, between May 1, 1989 and April 30, 1993, were included prospectively in the study. All patients were assessed before operation by an anaesthetist, wherever possible. Assignation of the 1963 ASA classification (table 1) was performed by two anaesthetists, of which at least one was a consultant. The standard anaesthetic record was used. Specific data retrieved from the anaesthetic record were: ASA classification; emergency or elective operation; the presence of specific preoperative disease states (anaemia, defined as haemoglobin concentration < 100 g litre^{-1} or arterial hypertension systolic pressure > 160 mm Hg); previous myocardial infarction; previous stroke; smoking (positive if > 20 cigarettes per week); severe bronchopulmonary disease (vital capacity or forced expiratory volume in 1 s $< 40\,\%$ of predicted); diabetes mellitus (all types requiring medication); acute or chronic renal failure (serum creatinine > 1.5 mg dl^{-1}); and major gastrointestinal diseases (e.g. ulcerative colitis, gastric or duodenal ulcer). Type of anaesthesia, operation performed, operating time (time from skin incision to wound closure) and intraoperative blood loss, as estimated by the anaesthetist, were also recorded.

Operations were classified according to the Hoehn system [11], as used frequently in Germany, into

Table 1 American Society of Anesthesiologists' (ASA) physical status classification

Class	Description
I	Healthy patient
II	Mild systemic disease—no functional limitation
III	Severe systemic disease—definite functional limitation
IV	Severe systemic disease that is a constant threat to life
V	Moribund patient unlikely to survive 24 h with or without operation

minor (e.g. repair of soft tissue wounds, perineal surgery), moderate (colostomy formation, cholecystectomy, herniotomy) or major (bowel resection, thoracic surgery, abdominal and peripheral vascular interventions). Preoperative investigations in all patients undergoing moderate and major operations included serum electrolyte (Na^+, K^+, Cl^-), creatinine and glucose concentrations, blood count (haemoglobin, packed cell volume, platelet count, leucocyte count), coagulation screen (prothrombin time, partial thromboplastin time), chest x-ray and an ECG. Also, all patients received cephazolin (Elzogram 2 g) i.v. and single-dose low molecular weight heparin (Dalteparin sodium 7500 i.v.) s.c. after induction.

Postoperative data were obtained by surgical interns and final year medical students. Attention was focused on pulmonary complications such as bronchopulmonary infection, as diagnosed by positive sputum culture or positive chest x-ray, or both, atelectasis or pleural effusion, as seen on the chest x-ray. Significant arrhythmias such as new atrial fibrillation or acute myocardial infarction confirmed by ECG changes and increases in CPK-MB enzymes were recorded as cardiac complications. Wound inflammation or a purulent wound discharge was recorded as a wound infection, and clinically apparent anastomotic leakage was also noted. Culture-positive urinary tract infections were also recorded.

The data were summarized into two groups. First, to allow comparison between ASA classification and perioperative variables, we recorded duration of operation, intraoperative blood loss, duration of postoperative ventilation, stay in intensive care, postoperative hospital stay, and rates of pulmonary complications, cardiac complications, wound infection, anastomotic leakage, urinary tract infection and in-hospital mortality (expressed as means). The second grouping allowed a univariate analysis of the relationship between the most prevalent preoperative disease states and the incident of major postoperative events. Finally, logistic regression was applied to the data to estimate the risk odds ratio of single and combined perioperative variables.

STATISTICAL METHODS

The Student's *t* test was used to quantify the difference in the means of independent perioperative variables between ASA classifications. Differences in the rates of complications between ASA classifications were assessed by Fisher's exact test. The significance of the impact of preoperative disease states on the development of a specific postoperative complication was also assessed by Fisher's exact test. The logistic regression model is explained in the appendix.

Results

A total of 6301 patients were operated on in the sample period and patient data are summarized in table 2. More than 75 % of patients were classified as ASA II or III (table 3). As only 15 patients (0.2 %) were classified as ASA V and as 14 of these patients died in hospital, they were excluded from statistical analysis on morbidity.

There were a total of 9136 pre-existing disease states in 6301 patients (table 4). The major preoperative disease states identified were arterial hypertension, smoking, severe bronchopulmonary disease and major gastrointestinal disease, each with an incidence of more than 20 %. The type of operation according to Hoehn system was 1004 (16 %) minor, 1695 (27 %) moderate and 3602 (57 %) major. All ASA V patients underwent major operations. The specific sites of operation are summarized in table 5. As an indication of the type of operation performed, the 1077 operations listed as "colon and rectum" included mainly partial and total colectomy, and the 1495 operations listed as "vascular" included aortic procedures and carotid surgery.

For perioperative variables in relation to ASA (table 6), we found an increase in duration of operation between ASA I and ASA II–IV combined ($P < 0.05$) and between ASA II and III ($P < 0.05$). Intraoperative blood loss was 5–20-fold greater in ASA IV than in ASA I–III groups ($P < 0.05$). We found a 2–6-fold increase in the duration of postoperative ventilation between individual groups ($P < 0.05$). Postoperative intensive care and total hospital stay of ASA II–IV patients were 1–5 and 7–11 days longer, respectively, than in ASA I ($P < 0.05$). We found a 2–3-fold incidence of postoperative bronchopulmonary complications in a stepwise manner through each ASA class ($P < 0.05$). A threefold increase in cardiac complications was found between individual classes I–IV ($P < 0.05$). The incidence of postoperative wound and urinary tract infections was 2–3 times greater in ASA classes II–IV than in ASA class I (I *vs* II–IV, $P < 0.05$). Postoperative anastomotic leakages were independent of ASA class. We found a significant 5–7-fold stepwise increase in hospital mortality per ASA class.

The relationship between specific preoperative disease states and individual postoperative complications is shown in table 7. Arterial hypertension and previous myocardial infarction implied a 50% increase in the rate of developing a cardiac complication, and previous myocardial infarction implied longer postoperative ventilation. Severe bronchopulmonary disease implied a significant increase in the chance of developing a cardiac or pulmonary complication and increased duration of postoperative ventilation. We did not find that smoking was a significant factor in the development of the four major postoperative complications.

The logistic regression analysis data are summarized in table 8. The highest risk odds ratios for developing a postoperative complication were associated with worsening ASA classification and a "major" *vs* a "moderate" or "minor" operation, as per the Hoehn classification. Particularly, assignation of ASA IV implied a risk odds ratio of 4.26, that is a 4.26 times higher risk of developing a postoperative complication than for ASA I. As-

signation of ASA II and III implied risk odds ratios of 1.57 and 2.25, respectively. A moderate increase in the risk odds ratio was also seen in patients with renal disease, anaemia, bronchopulmonary disease and in those undergoing emergency operations.

Discussion

The ASA classification has established itself as the most widely used patient risk assessment scheme in anaesthesia, despite being developed in 1941 by Saklad [1] for the purpose of statistical data management. The 1963 revision eliminated the emergency classes of the original version and an emergency operation is noted by placing an "E" after the remaining five classes. No other preoperative risk assessment scheme developed has achieved the same widespread use. Other internationally known patient scoring systems outside the field of anaesthesia include APACHE II [12], used widely in intensive care, but the need for a 24-h sampling period of 12 routine physiological measurements, age and previous health status underlies the unsuitability of this system for anaesthesia. The Physiological and Operative Severity Score for the enUmeration of Mortality and morbidity (POSSUM) was presented by Copeland, Jones and Walters in 1991 [13] and is based on a point score derived from 12 physiological and six operative severity score factors. The authors' intention was to develop a score to aid surgical audit and thus their method does not give the full score and the numerical estimate of the risk of mortality and morbidity until the outcome is known. In contrast, the ASA classification represents a simple estimation of physiological status without the need for clinical resources and can be applied to every patient before operation.

A major drawback of the ASA system is assessment of a patient's "correct" ASA classification by different anaesthetists and this was shown clearly by Owens, Felt and Spitznagel [14]. In their study, 304 anaesthetists were requested to classify 10 hypothetical patients and the mean numbers of patients rated identically by the authors and the responders was 5.9 (mode 6). To minimize this variability in our study, assignation of ASA class was performed by two experienced anaesthetists adhering strictly to the 1963 criteria (table 1). It is important to remember that these criteria do not take into account age and the complexity of operation, and there is no differentiation between a systemic disease that leads to operation and one that is an incidental chronic finding.

Few studies have examined the relationship between ASA physical status and perioperative morbidity. Cohen, Duncan and Tate [15] studied anaesthetic complications in the intraoperative period and in the recovery room (e.g. cardiac arrest, hypotension, aspiration). Tiret and Hatton [10] reported similar major complications during or within 24 h of anaesthesia. Both studies found significant correlations between these anaesthetic complications and patient ASA classification.

Our data identified several specific intra- and postoperative variables correlated significantly with ASA classification. Intraoperative blood loss, duration of postoperative ventilation, duration of intensive care stay, rates of pulmonary and cardiac complications, and in-hospital mortality showed significant increases as patient ASA defined status advanced from I to IV, with a 20–180-fold difference between ASA I and IV, and an average 2.8- and 3.7-fold difference in these variables between ASA II and III, and ASA III and IV, respectively. The high incidence of perioperative morbidity in ASA classes III and IV, especially pulmonary and cardiac complications (4–18%), supports the concept of directing therapy, particularly ventilatory support and other intensive care resources, towards these patients.

The correlation between ASA classification and postoperative mortality has been shown in several previous studies [3, 5–8] and was confirmed by our data. The published absolute mortality rates of the individual classes showed considerable variation, with 0–0.3% for ASA I, 0.3–1.4% for ASA II, 1.8–5–4% for ASA III, 7.8–25.9% for ASA IV and 9.4–57.8% for ASA V. This variation may be explained by differences in assessment of the patient's ASA physical status, patient population, sample size, operations performed and duration of postoperative monitoring. The latter is particularly important, as some of the older studies included only deaths occurring within the first 48 h [6] or within the first 7 days [5] after operation, while none covered the whole hospital stay. Thus these studies missed almost 50 % of postoperative in-hospital deaths occurring after the seventh postoperative day [3]. Often these limits are placed to assess the possible role of anaesthesia in postoperative mortality. In contrast, our data, with mortality rates of 0.1 % for ASA I, 0.7 % for ASA II, 3.5 % for ASA III, 18.3 % for ASA IV and 93.3 % for ASA V, were based on all deaths in hospital after surgical intervention, as we wished to quantify the total in-hospital risk.

Univariate analysis of four major preoperative disease states against individual postoperative complications (table 7) demonstrated their role in the development of complications in the related organ systems. This information is of little impact as patients usually have more have one significant pre-existing disease and it cannot be used to quantify the relative risk. Therefore, our study attempted to quantify the importance of specific risk factors in the evaluation of surgical outcome using multiple risk analysis as the appropriate statistical method. This was done as a means of eliminating the interference of these variables, as in previous studies [9, 12, 13]. The risk odds ratio (ROR), reflecting the relative increase in the complication risk of a single variable, was calculated by multivariate analysis and stepwise regression. The highest risk odds ratio of 4.26 was calculated for ASA IV, followed by ASA III (ROR 2.25), class of operation (ROR 1.86), ASA II (ROR 1.57) and emergency operation (ROR 1.24).

All other variables were of minor significance. Again, this highlights the value of the ASA classification system for the prediction of postoperative complications. A similar conclusion was reached by Pedersen and colleagues [4] who evaluated the possible relationship of 35 preoperative variables to only one event: the need for postoperative mechanical ventilation in a 3-month screening study. The best predictor of all variables was an ASA classification of greater than III. To assess the role of the complexity of an operation as an independent risk factor, previous studies divided the interventions into two groups (minor/major) [9], or into four groups (minor/moderate/major/major+) [13]. Applying the Hoehn classification [11], we differentiated three classes and found no significant difference between minor and moderate interventions, whereas major operations implied an almost doubled risk of complications.

The relative risk of 1.24 for patients undergoing emergency operations developing a postoperative complication was lower than risk odds ratios reported previously. Tiret and Hatton reported an ROR of 2.0 for intraoperative complications [10], Pedersen and colleagues 2.1 for the risk of postoperative ventilation [4] and Cohen, Duncan and Tate 4.4 for the risk of dying within 7 days [15] after an emergency operation.

Forrest and colleagues [16] showed that ASA classes III and IV were major predictors for severe cardiorespiratory outcome in a study which included only patients for elective surgery.

To extend the use of the multivariate risk analysis concept, the impact of more than one variable can be assessed using the formulae in the appendix, together with estimated regression coefficients derived from the logistic regression analysis of our data. This attempted quantification of "total" relative risk is of great value as it could lead to improvement in patient therapy.

Appendix

The goal of logistic regression analysis is to describe the relationship between a prospectively observed dichotomous outcome (the occurrence of a postoperative complication or not—the dependent variable) and a set of independent indicator variables (perioperative variables in our model) by modelling the probability "P" of the outcome by an expression of the form:

$$P = \frac{1}{1+e^{-g(X)}} \tag{1}$$

where $g(X) = \beta_0 + \beta_1 X_1 + \ldots + \beta_n X_n$, β_0 = model constant, $\beta_{1\ldots n}$ = regression coefficients (estimated by maximum likelihood methods) and $X_{1\ldots n}$ = independent predictor variables coding perioperative clinical risk factors.

In our model there are three types of predictor variables: (i) those coding the dichotomous state yes/no (i.e. presence or not) of known clinical variables before operation, such as broncho-pulmonary disease or an emergency operation; these are usually coded "1" if a clinically poorer status is present and otherwise "0"; (ii) those variables coding values of continuous variables such as duration of operation; (iii) those categorical or ordinal items, such as ASA classification, where "dummy" using $k-1$ indicator variables for k categories of the item is set up. To simplify our model, the reference category for ASA status was set to ASA 1 and indicator variables for ASA II, III and IV termed ASA (1), ASA (2) and ASA (3), respectively (table A1).

To calculate the risk odds ratio (ROR) for an outcome we use:

$$\frac{P}{1-P} = e^{g(X-x)} \tag{2}$$

which by substitution becomes ROR =

$$e^{\beta} \quad \text{or} \quad e^{c\times\beta} \text{ respectively} \tag{3}$$

and may be estimated for each risk pattern.

An estimator for the multiplicative change in the ROR when switching an indicator variable to poorer status, leaving the values of all other independent variables fixed, is given by the expression:

$$e^{\beta} \tag{4}$$

An estimator for 100 $(1-\alpha)$ % confidence interval for the ROR is given by:

$$e^{\beta \pm 1.96\,\mathrm{SE}(\beta)} \tag{5}$$

where $\mathrm{SE}(\beta)$ = standard error of the regression coefficient β belonging to the variable studied for the change in ROR.

To obtain an estimate of the ROR of multiple variables we used equation (4). For example, using table 8, the ROR for a population with the risk pattern (a):

Table A1 Indicator variables for ASA categories

ASA status	Indicator variables		
	ASA (1)	ASA (2)	ASA (3)
I	0	0	0
II	1	0	0
III	0	1	0
IV	0	0	1

(a) ASA = II

Emergency operation = yes
Bronchopulmonary disease = yes
Smoker = yes

relative to a population with risk pattern (b):

(b) ASA = I

Emergency operation = no
Bronchopulmonary disease = no
Smoker = no

and with equal values for all other risk variables, is estimated through:

$$e^{(0.45+0.21+0.26+0.15)} = 2.9 \approx 3 \qquad (6)$$

In terms of relative risk this indicates that a postoperative complication may occur approximately three times as often among patients with risk pattern (a) than among patients with risk pattern (b), assuming all other clinical risk factors are identical.

Time course of increased haemodilution in hypotension induced by extradural anaesthesia

D. DROBIN AND R. G. HAHN

Summary

Volume loading with crystalloid solution results in more pronounced haemodilution in patients who develop arterial hypotension during induction of extradural anaesthesia than in those who remain normotensive. The aim of this study was to describe the time course of this increase in haemodilution. Heart rate, systolic arterial pressure and blood haemoglobin concentration were measured every 3 min during the onset of extradural anaesthesia in 22 elderly men undergoing short urological operations. Fluid therapy consisted of 15 ml/kg body weight of Ringer's acetate solution. Patients with a decrease in systolic pressure of > 25% retained 50% (SD 12%) of the infused fluid in the circulation, while the others retained 36 (8%) ($P < 0.002$). In both groups, arterial hypotension was followed by increased haemodilution after a delay of as much as 15 min. This suggests that, despite volume loading, there is relative hypovolaemia throughout the development of hypotension. (*Br. J. Anaesth.* 1996; **77**; 223–226).

Key words

Anaesthetic techniques, extradural. Arterial pressure, hypotension. Blood, volume. Fluids, i.v. Blood haemodilution.

Haemodilution is frequently induced by volume loading with a crystalloid solution before lumbar extradural anaesthesia or spinal anaesthesia is induced. The aim is to prevent a decrease in arterial pressure (AP) by increasing blood volume. However, the body's handling of crystalloid solutions is altered during the onset of these neural blocks. Elderly men who maintain a normal AP retain about 30 % of the solution given for volume loading in the circulation, while this fraction is twice as large in those who show a decrease in AP [1–3]. Thus blood volume increases in proportion to hypotension. Marked haemodilution has also been described in parturients who develop hypotension during onset of these blocks before Caesarean section [4].

The aim of this study was to see how fast this increased haemodilution develops.

Patients and methods

We studied 22 male patients, ASA I–II, mean age 71 (range 38–85) yr, during induction of extradural anaesthesia before short urological operations. Approval of the Ethics Committee was obtained and each patient gave informed consent.

Premedication consisted of oral oxazepam 25 mg orally. Cannulae were inserted into the antecubital veins of both arms. A fluid load of 15 mg/kg body weight of an isotonic glucose-free crystalloid solution (Ringer's acetate) was infused into one of these veins at a constant rate over 50 min with the aid of two infusion pumps (IVAC 560, San Diego, CA, USA). After 20 min, extradural anaesthesia was induced with 2 % mepivacaine and adrenaline 1:200000 (Carbocain–adrenalin, Astra, Södertälje, Sweden). A test dose of 3 ml of the anaesthetic solution was administered into the extradural space via an indwelling catheter when 20 min had elapsed since the onset of volume loading. The main dose was 9–16 ml, depending on body weight, and was given 3 min later.

A blood sample for measurement of blood haemoglobin concentration (Hb) with a Coulter Counter S plus (Counter Electronics, Hialeah, FL, USA; coefficient of variation of 2 %) was obtained on 13 occasions, before any fluid was given, at 10 min and just before the test dose was given at 20 min into volume loading. Thereafter, Hb was measured every 3 min up to 50 min into the study, at which time the fluid had been infused and adequate surgical analgesia had been achieved, as determined by loss of pinprick sensation.

On the same occasions, one of the authors (D.D.) measured systolic AP using a mercury sphygmomanometer. Hypotension was defined as a decrease in systolic AP of > 25 %. Patients who did not fulfil this criterion were considered normotensive. A vasopressor was available for those who developed bradycardia or nausea, but this did not occur.

The amount of fluid infused that remained in the circulation was calculated from the following equation [1–3]:

$$\text{Fluid retained (\%)} = (V_0(\text{Hb}_0/\text{Hb}_n) - V_0)/\text{volume infused}$$

where Hb_0/Hb_n = haemodilution and V_0 = blood volume before treatment, as estimated from the height and weight of the patient [5].

The results are expressed as mean (SD). The methods of statistical evaluation were simple and multiple linear regression analysis, one-way ANOVA and the paired *t* test were used. $P < 0.05$ was considered statistically significant.

Results

Ten patients developed hypotension during the onset of extradural anaesthesia. There were no significant differences between these patients and normotensive patients in age, systolic AP or the amount of anaesthetic solution given (table 1). However, the extent of analgesia was higher in hypotensive patients, and they retained a larger fraction of the infused fluid in the circulation than normotensive patients.

Table 1 Patient data, systolic arterial pressure (SAP) and amount of fluid infused that was retained in the blood of 22 elderly men in whom lumbar extradural anaesthesia was induced (mean (SD or range)). * SAP decreased to > 25% during the onset of block

	Normotensive	Hypotensive*	ANOVA
n	12	10	
Age (yr)	72 (52–82)	69 (38–85)	
Weight (kg)	80 (13)	77 (13)

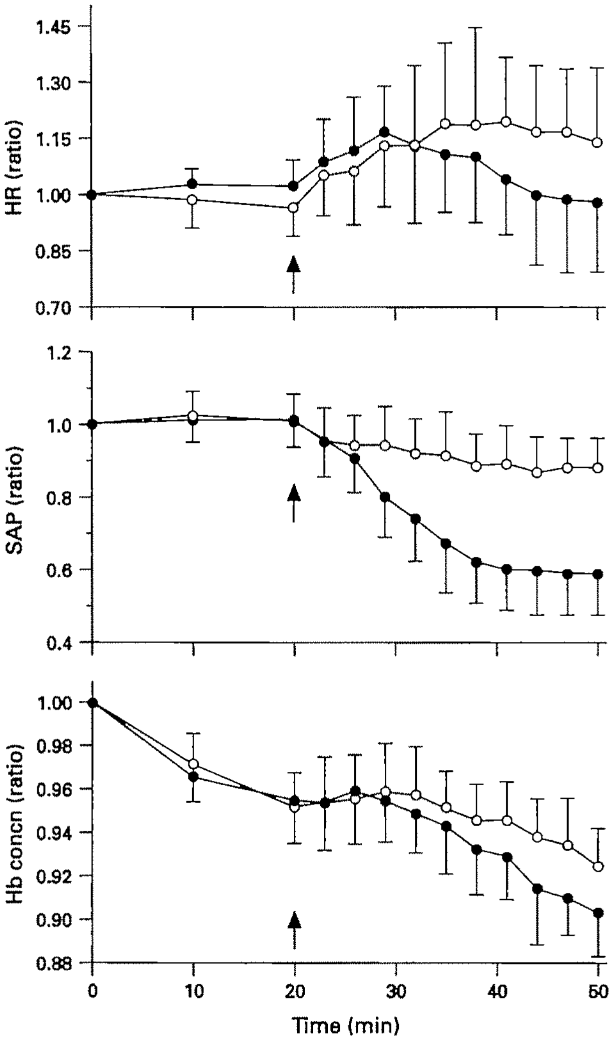

Figure 1 Relative changes in heart rate (HR), systolic arterial pressure (SAP) and haemoglobin (Hb) concentration during volume loading with Ringer's acetate solution and induction of extradural anaesthesia (arrows) in 22 elderly men (mean, SD). Ten patients showed a total decrease in SAP of > 25% (●) while 12 showed a less pronounced decrease (○).

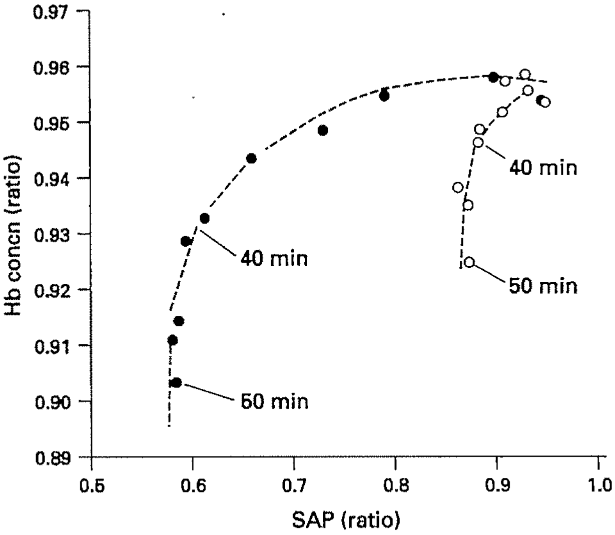

Figure 2 Relative change in systolic arterial pressure (SAP) *vs* haemoglobin (Hb) concentration after the local anaesthetic solution had been injected into the extradural space. The distance between each point on the curves represents a period of 3 min. Data are mean ($n = 22$) and are divided into hypotensive (●) and normotensive (○) patients.

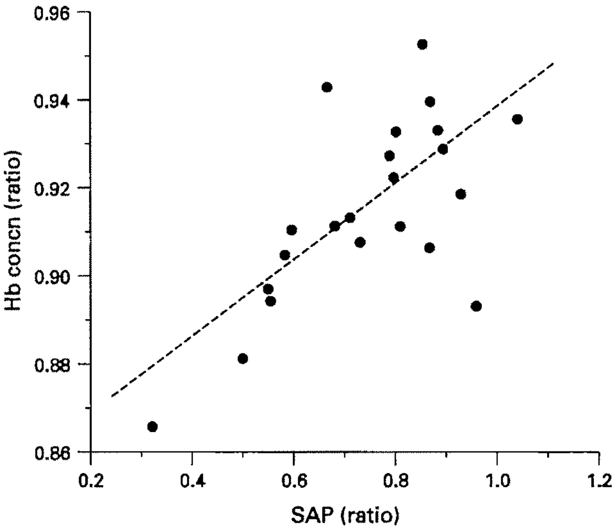

Figure 3 The decrease in systolic arterial pressure (SAP) *vs* haemoglobin (Hb) concentration from before volume loading with Ringer's acetate solution to after extradural anaesthesia had been induced 50 min later. Each point represents one patient ($r = 0.66$, $P < 0.001$).

Heart rate increased significantly during the onset of block in the normotensive patients (paired t test) but remained unchanged in those who showed a decrease in AP (fig. 1, top). The time courses of the changes in systolic AP and haemodilution were the same, irrespective of the magnitude of the hypotensive reaction (fig. 1, middle and bottom). A plot of SAP *vs* haemodilution over time highlights the fact that the time courses in both the hypotensive and normotensive patients consisted of two distinctly different phases, each with a duration of approximately 15 min (fig. 2). The first phase was characterized by a decrease in AP and the second by haemodilution.

The end result (at 50 min) showed a significant linear relationship between the reductions in AP and Hb in all patients (fig. 3). Multiple regression analysis confirmed that no other factor, including haemodilution during the initial 20 min of volume loading ($P = 0.12$) and baseline AP ($P = 0.39$), correlated with haemodilution during the onset of the block. There was no correlation between the initial haemodilution and hypotension.

Discussion

Inadequate circulating blood volume is still believed to be the main mechanism responsible for hypotension during the onset of extradural anaesthesia. [6]. Blood is pooled in the capacitance vessels of the legs at the expense of cardiac filling [7]. The increased haemodilution in hypotensive patients probably indicates an altered relationship in compliance for volume expansion between the intravascular fluid compartment and the interstitial fluid, to the advantage of the dilated intravascular fluid compartment. As vasodilatation is more widespread in patients with high-level extradural block, they also have more haemodilution.

This study showed that the fluid shift typical of vasodilatation develops more slowly than expected. To maintain venous return, each incremental increase in vascular capacitance would have to be followed by prompt and proportional haemodilution, but this apparently does not occur. Increased haemodilution is a dynamic process that can be regarded as two successive phases of change in the relationship between AP and Hb concentration. The most rapid reductions in AP and Hb differed by as much as 15 min. The delay before hypotension was followed by haemodilution, suggesting that relative hypovolaemia persisted throughout the onset of extradural anaesthesia. Therefore, our findings might be relevant to the fact that volume loading is ineffective in preventing hypotension [8–10].

The delay before haemodilution developed can perhaps be understood by considering the origin of the fluid that appeared in the circulation of hypotensive patients. Several possibilities exist. Hypovolaemia is capable of recruiting appreciable amounts of fluid from skeletal muscle and skin [11], but this is not consistent with the essentially unchanged Hb concentration when extradural anaesthesia is induced in the absence of volume loading [1].

Another potential source of the fluid is the interstitial fraction of Ringer's acetate solution infused during the first 20 min of the study. "Autotransfusion" with interstitial fluid, is a rapid process if the capillary pressure is lowered [11] and can hardly explain the delay in haemodilution. This mechanism does operate to some degree, however, as evidenced in a few patients in whom volume loading was terminated just before the local anaesthetic was injected.

A third possibility is that the fluid for increased haemodilution is derived mainly from the ongoing infusion. This view serves best to explain the 15-min delay between hypotension and haemodilution. It also receives support from a recent study in which hypotension promoted a deviation in blood glucose concentration towards the glucose concentration of the crystalloid infusion (being 0 to 0.5%), thus indicating excess enrichment of the ongoing infusion in the blood of hypotensive patients [12].

The use of a local anaesthetic solution that contained adrenaline is not likely to have affected the hypotension–haemodilution relationship found in this study [1]. Absorption of adrenaline may explain the tachycardia observed just after the induction, while block of cardiac sympathetic fibres by high-level analgesia can account for the difference in heart rate between the hypotensive and normotensive patients. Adrenaline can probably also account for the mild transient haemoconcentration observed after the local anaesthetic solution had just been injected.

Atrial natriuretic peptide released during initial volume loading is a possible factor augmenting hypotension by reducing vascular tone and increasing vascular permeability [13, 14]. Such an effect could not be discerned statistically, however, as pronounced volume expansion before extradural anaesthesia did not correlate with hypotension.

One should be aware of the artificial division between patients who showed a decrease in systolic AP of more or less than 25%. However, a reduction in systolic AP to a predetermined physiological level, such as < 100 mm Hg or a decrease of 20–30% below baseline, appears to be conventional in this type of study [15]. The categorical approach was used here only to achieve the highest possible degree of clarity in the presentation. Figure 3 shows that the hypotension–haemodilution relationship is in fact a continuous linear function, and our slope agreed well with those of previous reports [1–3].

LABORATORY INVESTIGATIONS

Combination of inhaled nitric oxide with i.v. nitroglycerin or with a prostacyclin analogue in the treatment of experimental pulmonary hypertension

L. J. VAN OBBERGH, M. CHARBONNEAU AND G. BLAISE

Summary

We have studied the effect of combining inhaled nitric oxide (NO) with an i.v. vasodilator agent, nitroglycerin, or ciloprost, a prostacyclin analogue, during acute pulmonary hypertension in pigs, induced by continuous infusion of a thromboxane analogue (U46619), adjusted to maintain mean pulmonary artery pressure (MPAP) at 40 mm Hg. The effects of the different treatments on MPAP and pulmonary resistances were determined. In the first part of the study, we determined the dose–response to increased NO concentrations from 5 to 40 ppm. This showed a maximum pulmonary effect with NO 5 ppm, but with no systemic effects. The effect of NO 10 ppm was then compared with two i.v. drugs. Nitroglycerin was less effective than NO on pulmonary vessels but induced significant arterial hypotension. Pulmonary vasodilatation induced by ciloprost was greater than that by NO but with the same side effects as nitroglycerin on systemic variables. We also found that the combination of NO and nitroglycerin had the same pulmonary effects as NO 10 ppm but that adding ciloprost to NO decreased pulmonary pressures significantly more than either drug used alone. We conclude that inhaled NO may be usefully combined with i.v. ciloprost but not with i.v. nitroglycerin. (*Br. J. Anaesth.* 1996; **77**: 227–231)

Complications, pulmonary hypertension. Pharmacology, nitric oxide. Pharmacology, nitroglycerin. Hormones, prostaglandins. Pig.

Pulmonary vasoconstriction after cardiopulmonary bypass should be treated rapidly as it causes right ventricular failure [1]. Under normal physiological conditions, the endothelium maintains low pulmonary vascular resistances by producing two potent vasodilators, endothelium-derived relaxing factor (EDRF) and prostacyclin [2]. The effect of these two substances is similar: they relax vascular smooth muscle, although via different pathways. Prostacyclin stimulates adenylate cyclase thus increasing cAMP concentrations [3]. This second messenger activates cAMP-dependent protein kinase to modify phosphorylation of myosin and relax smooth muscle. In contrast, EDRF (which is nitric oxide) stimulates cytoplasmic guanylate cyclase increasing cyclic guanosine monophosphate (cGMP) concentration, which is another second messenger that relaxes vascular smooth muscle, after activation of cGMP-dependent protein kinase. The endothelial cell, therefore, plays a crucial role in the control of pulmonary vascular tone, as reviewed recently by Loscalzo [4].

The inflammatory response initiated by cardiopulmonary bypass activates the granulocytes and their secretion of oxygen radicals damages the endothelial cell, thus contributing to the development of pulmonary hypertension [5]. The release of thromboxane A_2 by platelets and the heparin–protamine reaction further complicate this situation [6]. It has also been shown that the response to a thromboxane analogue (U46619) is increased for 2 days after experimental cardiopulmonary bypass in dogs [7]. Nitrates, prostacyclin or, more recently, inhaled nitric oxide (NO) [8] have been used successfully to treat this acute complication. Recently, it has been reported that inhaled NO associated with prostacyclin could have a synergistic effect in the treatment of pulmonary hypertension associated with correction of a congenital aortic stenosis [9].

Therefore, in this study, we determined if combining inhaled NO with either i.v. nitroglycerin or i.v. ciloprost, a synthetic analogue of prostacyclin (PGI_2), would enhance the pulmonary vasodilator effect.

Materials and methods

This study was approved by our Institutional Research and Animal Welfare Committee. All animals were treated according to the Canadian Animal Protective Council Guidelines.

Female pigs, weighing 20–25 kg, were anaesthetized with ketamine 15 mg kg^{-1} i.m. After a bolus of fentanyl 5 $\mu g\ kg^{-1}$, ventilation was controlled mechanically via a tracheostomy.

L. J. VAN OBBERGH*, MD, M. CHARBONNEAU, MD, G. BLAISE, MD, Department of Anaesthesia, Notre Dame Hospital, University of Montreal, Montreal, Quebec, Canada. Accepted for publication: February 19, 1996.

*Present address for correspondence: Department of Anaesthesiology, Catholic University of Louvain Medical School, 10 av. Hippocrate, 1200 Brussels, Belgium.

Tidal volume was set at 15 ml kg^{-1} and the frequency adjusted to maintain Pa_{CO_2} at 4.6–6.0 kPa. FI_{O_2} was maintained at 30%. Anaesthesia was maintained with infusions of fentanyl and pentobarbitone; to decrease its cardiovascular effects, pancuronium was combined with tubocurarine to provide neuromuscular block. Lactated Ringer's solution was infused at 15 ml h^{-1}.

Mean systemic arterial pressure (MAP) was recorded via the carotid artery. A pulmonary artery catheter (5-French gauge) was introduced into the pulmonary artery via the internal jugular vein. Catheters (12-French gauge) were inserted by sternotomy into the main pulmonary artery and into the left atrium to record, respectively, mean pulmonary artery pressure (MPAP) and left atrial pressure (LAP). All pressures were measured with Abbot (Abbott, Montreal, PQ, Canada) transducers. Cardiac output was recorded as the average of three thermodilution measurements obtained after injection of saline 5 ml kept at 4 °C.

Inhaled NO was provided by adding a mixture of NO and nitrogen to the air entry of a Puritan Bennett 1200AE respirator. NO concentrations were measured by chemiluminescence (TECAN ciloprost D 700AL analyser, AMKO Inc., Ontario, Canada), sampling in the inspiratory limb of the respiratory circuit.

The animal was allowed to stabilize for 30 min after surgery, after which pulmonary hypertension was induced by continuous infusion of a thromboxane analogue (U 46619: Upjohn, Kalmazoo, MI, USA) at 20 µg ml^{-1} diluted in 0.9% saline into a separate vein in the ear. The infusion rate was adjusted to maintain a stable MPAP of 40 mm Hg for 20 min.

DETERMINATION OF THE DOSE–RESPONSE CURVE TO NITRIC OXIDE

To determine the optimum inhaled NO concentration to be used during comparisons with the i.v. drugs, we established a dose–response curve for NO in our model by increasing the NO concentration from 5 to 40 ppm. Each experiment was therefore separated into seven periods of 20 min starting when a stable condition was observed for at least 10 min after any therapeutic modification: (1) basal status; (2) pulmonary hypertension as described above; (3) inhaled NO concentration set at 5 ppm; (4) at 10 ppm; (5) at 20 ppm; (6) at 40 ppm; and (7) return to the second stage discontinuing NO.

The inhaled NO concentration was increased cumulatively. Haemodynamic variables (MAP, MPAP, LAP, CO) were recorded every 5 min during each period. Seven pigs were included in this preliminary study.

COMPARISON BETWEEN THE EFFECT OF NO 10 PPM AND THE MAXIMUM EFFECT OF EITHER NITROGLYCERIN OR PROSTACYCLIN INFUSION

Pulmonary hypertension was initiated in 14 pigs as described previously and treated for 20 min with 10 ppm of inhaled NO, which was then stopped to allow recovery of pulmonary hypertension. The animal was then allocated randomly to receive either an infusion of nitroglycerin 400 µg ml^{-1} diluted in 5% glucose ($n = 7$) or an infusion of ciloprost (Iloprost, Berlex, St Laurent, PQ, Canada) 10 µg ml^{-1} diluted in 0.9% saline ($n = 7$). These infusions via the jugular vein were started with nitroglycerin 1 µg kg^{-1} min^{-1} or ciloprost 0.1 µg kg^{-1} min^{-1} and increased progressively until we observed either a return of MPAP to basal values or a 20% reduction in basal MAP. When this occurred, the infusion was kept constant for 20 min to record haemodynamic variables and arterial blood-gas tensions. After this period, NO 10 ppm was reintroduced for 20 min to assess any beneficial effect of the combination of the two drugs. All treatments were then discontinued to restore pulmonary hypertension.

Pulmonary (PVR) and systemic (SVR) vascular resistances were calculated, respectively, according to the formulae:

$$(\text{MPAP} - \text{LAP})/\text{CO} \times 79.9 \text{ and}$$
$$(\text{MAP} - \text{CVP})/\text{CO} \times 79.9$$

All data are presented as mean (SEM). Statistical analysis comprised analysis of variance for repeated measures. Bonferroni's method was used for *post hoc* multiple comparison when analysis of variance was significant. $P \leqslant 0.05$ was considered significant.

Results

Data recorded during determination of the dose–response to inhaled NO are summarized in table 1. MPAP and PVR were increased significantly by U46619 compared with baseline values. However, there were no changes in MAP and SVR after infusion of the thromboxane analogue.

The dose–response curve to inhaled NO 5–40 ppm showed a maximum effect on pulmonary artery pressure at the 5 ppm concentration; increasing NO concentration did not alter significantly either MPAP or PVR compared with the initial concentration. From this dose–response curve and as the effect of inhaled NO reached a plateau starting at 5 ppm, a concentration of 10 ppm of inhaled NO was chosen as supramaximal stimulation to evaluate its effect when combined with the i.v. drugs.

In the second part of the study, when a constant dose of NO 10 ppm was inhaled, pulmonary artery pressure decreased by 29 (2)% in the group receiving nitroglycerin and by 27 (3)% in the group receiving ciloprost, while PVR decreased by 44 (4)% in the nitroglycerin group and by 49 (5)% in the ciloprost group.

Data recorded in the nitroglycerin group are summarized in table 2 and those in the ciloprost group in table 3, while table 4 shows the effect of different treatments for pulmonary hypertension on MPAP and PVR. The decrease induced by treatment is expressed as a percentage of the value recorded during pulmonary hypertension.

The mean maximal dose of nitroglycerin infused was 2.5 (0.15) µg kg^{-1} min^{-1}, while for ciloprost it was 0.32 (0.02 µg kg^{-1} min^{-1}. Nitroglycerin infusion

Table 4 Variations in pulmonary pressures (MPAP) and resistances (PVR). The decrease induced by treatment is expressed as a percentage of the value recorded during the pulmonary hypertension stage. NO 10 ppm = effect of 10 ppm inhaled NO; drug = effect of the i.v. drug, either nitroglycerine (NTG) or ciloprost (CL); NO–drug = effect of the combination of the i.v. drugs with 10 ppm inhaled NO. *$P < 0.05$ compared with NO 10 ppm; †$P < 0.05$ compared with drug

	MPAP			PVR		
	NO 10 ppm	Drug	NO–Drug	NO 10 ppm	Drug	NO–Drug
Group NTG	−44 (4)	−22 (6)*	−43 (2)†	−29 (2)	−29 (2)	−31 (2)
Group CL	−49 (5)	−70 (4)*	−81 (4)*†	−27 (3)	−39 (2)*	−47 (4)*†

alone decreased MPAP and PVR, respectively, by 29 (2)% and 22 (6)% (table 2). For ciloprost infusion alone, MPAP was decreased by 39 (3)% and PVR by 70 (4)%. Hence, the variations induced by infusion of ciloprost were significantly greater for both MPAP and PVR than those produced by nitroglycerin.

Comparing the variations induced by inhaled NO alone with those induced by the combination of inhaled NO and nitroglycerin, there were no significant differences for either MPAP or PVR. The effects observed with the combination of inhaled NO and ciloprost were, however, significantly greater for MPAP and PVR than those recorded when only inhaled NO was provided. This combination was also significantly more effective on these variables than when ciloprost alone was infused.

We found that MAP and SVR were not altered significantly by inhaled NO. Infusion of nitroglycerin, however, decreased MAP by 25 (4)% and SVR by 22 (4)% while they decreased by 10 (4)% and 30 (7)%, respectively, with infusion of ciloprost. The combination of inhaled NO with either of the two i.v. agents did not alter significantly MAP or SVR.

Return to baseline MPAP was seen in one of seven pigs treated with nitroglycerin and in five of seven pigs when ciloprost was infused. This suggests that the decrease in SAP was the limiting factor for the increase in infusion in six pigs in the nitroglycerin group and in two pigs in the ciloprost group, these values being significantly different (Fisher's exact test: $P = 0.029$).

In both groups only inhaled NO improved Pa_{O_2} significantly compared with values obtained during pulmonary hypertension (tables 2, 3).

Discussion

In the first part of this study, we confirmed the effectiveness and selectivity of inhaled NO as a pulmonary vasodilator. A concentration of 5 ppm significantly decreased pulmonary pressure with no effect on systemic variables, as described previously by Frostell and colleagues [10]. We also observed that in our model of pulmonary hypertension induced by a thromboxane analogue, increasing the inhaled NO concentration from 5 to 40 ppm did not significantly increase pulmonary vasodilatation.

Our second set of experiments showed that ciloprost appeared to be more effective than inhaled NO or nitroglycerin in reducing pulmonary hypertension while inhaled NO in combination with i.v. nitroglycerin did not enhance its efficacy. In contrast, the combination of inhaled NO and i.v. ciloprost revealed some additive effect of these two drugs.

Nitroglycerin is an i.v. drug used commonly to treat pulmonary hypertension. The use of i.v. nitrovasodilatators is, however, often limited by systemic effects. Inhaled NO has the unique advantage of pulmonary selectivity as it is rapidly inactivated because it is bound tightly to haemoglobin [11]. Moreover, being distributed only to the ventilated regions of the lung, inhaled NO reduces intrapulmonary shunting, as shown by the increase in Pa_{O_2}. The i.v. vasodilators increase venous admixture which normally results in a decrease in Pa_{O_2} [12], but our study did not show this side effect, probably because most of our pigs were free from chest disease and intrapulmonary shunt was minimal [13].

Nitroglycerin acts only after intracellular release of NO [14], which implies that these two drugs share the same mechanism of action via activation of the cGMP pathway. Our study suggests that relaxation of the vascular smooth muscle cell by cGMP reaches a plateau, which was achieved in our model with 5 ppm of inhaled NO. This was confirmed further by the fact that adding another i.v. drug which acts via the same pathway did not increase pulmonary vascular dilatation.

Prostacyclin is the other i.v. drug used widely to treat primary or secondary pulmonary hypertension in adults and children [15]. Recently, its aerosolized form has been administered successfully for the treatment of pulmonary hypertension in an animal model [16] and in children suffering from acute respiratory syndrome [17]. Two synthetic analogues with short half-lives have been developed: epoprosterenol and ciloprost. They produce the same pharmacological activities of natural prostacyclin, including peripheral vasodilatation, inhibition of platelet aggregation and some cytoprotection. These compounds bind to membrane prostacyclin receptors and stimulate adenylate cyclase. The subsequent increase in cAMP concentration relaxes smooth muscle. It has also been suggested that prostacyclin hyperpolarizes the membrane of the smooth muscle cell to produce relaxation.

In our study, we observed that ciloprost reversed induced pulmonary hypertension more frequently than nitroglycerin. This does not imply that ciloprost is more powerful than nitroglycerin but that ciloprost has greater pulmonary selectivity, which was confirmed by the fact that the progressive increase in the i.v. infusion was not limited as frequently by systemic hypotension in the ciloprost group compared with the nitroglycerin group; another explanation may be improved cardiac contractility secondary to the increase in the intracellular cAMP concentration, while NO and cGMP have negative inotropic actions [18].

We found a cumulative effect of ciloprost and inhaled NO on the decrease in MPAP and PVR. The synergistic action between NO and ciloprost has been demonstrated previously on isolated coronary arteries, in which PGI_2 relaxation was potentiated by the presence of the vascular endothelium [19]. This effect has also been shown in the hamster microcirculation where the combination of drugs increasing cAMP and drugs increasing cGMP were more effective than either drug alone [20]. This may be explained by the fact that NO activates the GMP pathway whereas ciloprost stimulates adenylate cyclase and the AMP pathway. The combination of NO and ciloprost has been reported to be useful in some case reports [9] but a careful assessment of the benefit of this association has not yet been reported.

Role of prostaglandins and nitric oxide on halothane-induced arteriolar dilatation in rat diaphragm

V. de Larminat, J. Boczkowski, B. Dureuil, E. Vicaut, R. Farinotti, M. Aubier and J.-M. Desmonts

Summary

The effects of anaesthetics on the microcirculation of the diaphragm are incompletely understood. Therefore, we assessed by *in vivo* intravital microscopy in rats the action of halothane on diaphragmatic arteriolar diameter and the role of nitric oxide and prostaglandins on halothane-induced diaphragmatic arteriolar diameter. We studied 54 rats anaesthetized with thiopentone. Dose–response curves to topically applied Krebs' solution saturated with halothane at increasing concentrations of 0%, 1%, 3% and 5% were carried out in the presence of an inhibitor of nitric oxide synthesis (*N*ω-nitro-L-arginine (LNA), 300 μmol litre^{-1}) or inhibitors of prostaglandin synthesis (mefenamic acid 20 μmol litre^{-1} or indomethacin 20 mol litre^{-1}) or in the absence of any inhibitor. We found dose-dependent arteriolar dilatation which was abolished by mefenamic acid and indomethacin. In contrast, the effect of halothane was not modified by LNA. These data demonstrated that halothane-induced arteriolar dilatation in the diaphragm of the rat was mediated by prostaglandins but not by nitric oxide. (*Br. J. Anaesth.* 1996; **77**: 232–237)

Key words

Anaesthetics volatile, halothane. Hormones, prostaglandins. Pharmacology, nitric oxide. Muscle respiratory. Rat.

Halothane is commonly considered as a pure vasodilator. However, animal and human studies *in vivo* have shown that halothane has different effects in vascular beds [1–3]. Miller, Kistner and Epstein [2] showed in rats that inhalation of halothane induced an increase in blood flow to the brain, kidney and liver, and a decrease in blood flow to the heart and peripheral and respiratory skeletal muscles. In a previous work we showed that inhalation of halothane was unable to dilate the arterioles of the diaphragm [4]. These differences in vascular responses to inhalation of halothane observed *in vivo* may be related to differences in the sensitivity of vascular beds to this agent [5]. Alternatively, they may reflect differences in local vascular adaptation to the haemodynamic changes induced by halothane. Therefore, we assessed the vascular effects of halothane on diaphragmatic microcirculation.

In this study we assessed the direct effects of halothane on diaphragmatic arteriolar diameters, by topical administration on the surface of the diaphragm in order to avoid its systemic haemodynamic action and evaluated the mechanism(s) of action of halothane on diaphragmatic arterioles. We were interested in the role of the vascular endothelium because it has been shown recently that halothane modulates endothelium-dependent relaxation [6]. Therefore, we assessed the role of endothelial agents, such as nitric oxide and prostaglandins, on halothane-induced diaphragmatic arteriolar diameter by inhibition of nitric oxide synthesis with *N*ω-nitro-L-arginine (LNA) [7, 8] and prostaglandin synthesis with mefenamic acid or indomethacin [9]. Special emphasis was placed on evaluation of the effects of prostaglandins, as these agents contribute, together with nitric oxide, to modulation of diaphragmatic arteriolar tone [10], a phenomenon which could not be detected in other skeletal muscle microvessels [11, 12].

Materials and methods

Male Sprague–Dawley rats weighing 163 (5) g were anaesthetized with sodium pentobarbitone 50 mg/kg body weight i.p. A patent airway was maintained with a tracheostomy tube and the lungs were ventilated throughout the study with a rodent ventilator (Ugo Basile Apparatus Inc., Italy) at an $F_{I_{O_2}}$ of 0.5. The left carotid artery was cannulated for continuous arterial pressure monitoring with a Statham P23 DB transducer. All animals whose mean arterial pressure decreased to less than 90 mm Hg were excluded from the study. The right jugular vein was cannulated for administration of 5 ml kg^{-1} normal saline during surgery. Body temperature was monitored continuously with a rectal

probe and maintained constant at 36.5–37.5 °C by a heat lamp and a heating pad (Harvard Apparatus, MA, USA).

The experimental design was in agreement with the recommendations of French Law (Ministère des Affairs Sociales et de la Solidarité Nationale) and all experiments were approved by the local Animal Committee.

PREPARATION OF THE DIAPHRAGM

The diaphragm preparation has been described in detail previously [10, 13]. Briefly, a bilateral thoracotomy was performed in the fifth intercostal space, the sternum remaining intact. The diaphragm was separated carefully from the lungs and the mediastinal tissues. A midline laparotomy was followed by a transverse incision at each side which allowed exposure of the diaphragm in a perpendicular position relative to the body of the animal. The animal was placed in a Trendelenburg position on a rodent operating table (Harvard Apparatus, MA, USA).

When the diaphragm was exposed, its abdominal face was irrigated continuously with a modified Krebs–Henseleit solution containing (mmol litre^{-1}): NaCl 118, KCl 5.9, $CaCl_2$–$2H_2O$ 2.5, $MgSO_4$–$7H_2O$ 0.5, $NaHCO_3$ 28 and glucose 10. This solution was maintained at 37.5 °C and pH, $P\text{O}_2$ and $P\text{CO}_2$ were, respectively, fixed at 7.41 (0.06), 3.1 (0.2) kPa and 5.5 (0.1) kPa by bubbling with a 5 % carbon dioxide–95 % nitrogen gas mixture. Pancuronium 4 μmol litre^{-1} was added to Krebs' solution to prevent muscle fasciculation.

The muscle was transilluminated using a 150-W tungsten–halogen lamp connected to a fibreoptic cold light microprobe introduced gently through the left thoracotomy aperture. The diaphragmatic microcirculation was observed with a modified Leitz microscope placed in a position parallel to the area of the abdominal side of the muscle. The image, magnified by a 20 × long-distance objective, was projected into a CCD video camera (Sony DXC-101P) connected to a videotape recorder (Sony VO-9600 P) and a video monitor (Sony PVM-1371 QM). Total magnification from the vessel image to the monitor was × 600. Arteriolar diameters were measured by playback analysis of the video record using the technique of Intaglietta and Tompkins [14] and, after completion of the experimental procedures, the microvascular images were read by one of the investigators who was blinded to the sequence of experimental steps.

We studied changes in the diameter of the arteriolar branches arising from the internal mammary and intercostal arteries. Second and third arteriolar orders (A2 and A3, respectively) were analysed according to the number of bifurcations proximal to the studied arterioles, as described previously [15]. Only clearly distinguishable vessels were selected and the number of measured arterioles varied between one and three of each order per preparation. Before any measurement, a 20–30-min period after surgery was allowed to reach a steady state of arteriolar tone.

EXPERIMENTAL DESIGN

Two studies were performed.

Study 1

In seven animals arteriolar diameter was measured at baseline and then Krebs' solution saturated with increasing concentrations (0 %, 1 %, 3 % and 5 %) of halothane was applied topically in order to perform a cumulative dose–response curve. The different concentrations were administered in a stepwise manner for 2 min each. The diameter of the selected arteriole was measured at the end of each administration. This was followed by a 15-min wash-out period during which the muscle was irrigated with drug-free Krebs' solution. At the end of this period, the diameter of the same arterioles studied previously was measured and a second cumulative dose–response curve to halothane was performed in order to evaluate the reversibility of the effects of halothane.

Study 2

Twenty-eight animals were allocated to one of four groups according to topical administration on the diaphragm of Krebs' solution containing LNA 300 μmol litre^{-1} ($n = 7$ animals, group LNA), mefenamic acid 20 μmol litre^{-1} ($n = 7$ animals, group MA), indomethacin 20 μmol litre^{-1} ($n = 7$) or no inhibitor ($n = 7$ animals, group C). Diameter was measured at baseline and after a 20-min superfusion period. Then, Krebs' solution saturated with increasing concentrations (0 %, 1 %, 3 % and 5 %) of halothane was applied topically in order to perform a cumulative dose–response curve, as described above. The inhibitors corresponding to each pretreatment group were also present in the halothane-saturated Krebs' solutions. The diameter of the selected arteriole was measured at the end of each application.

DOSE OF HALOTHANE

Samples of Krebs' solution equilibrated with halothane were removed at the end of an application period for subsequent measurement of anaesthetic concentration in Krebs' solution by gas chromatography [16].

REAGENTS

Halothane was obtained from Laboratoires Belamont (Paris, France) and was introduced into 40 ml of Krebs' solution at 37 °C by bubbling with 5 % carbon dioxide–95 % nitrogen passed through a precalibrated vaporizer (flow 0.5 litre min^{-1}) for 15 min. Vaporizers delivered halothane at 0 %, 1 %, 3 % and 5 %. Mefenamic acid and LNA were obtained from Sigma Chemical Co. (St Louis, MO, USA). Mefenamic acid was dissolved in sodium carbonate 1 mg ml^{-1} and diluted to the final concentration with Krebs' solution. LNA was dissolved directly in

Krebs' solution by stirring at room temperature. Indomethacin was obtained from Merck, Sharp and Dohme Chibret Products, France. Drug solutions were prepared freshly daily.

STATISTICAL ANALYSIS

All results are expressed as mean (SD). Comparison between arteriolar diameters at baseline in the different groups of animals was performed by one-way analysis of variance. Evaluation of the effects of each inhibitor on baseline arteriolar diameter was performed by a paired *t* test. Comparison between arteriolar dose–response curves (diameter *vs* dose of halothane) between the different groups of animals was performed using two-way analysis of variance for repeated measures, one "within" factor, that is factor "dose" and a grouping factor "absence or presence of inhibitor" [17]. $P < 0.05$ was considered significant.

Results

The experimental interventions did not affect systemic arterial pressure, which was stable over the course of the experiments and within the range 95–120 mm Hg.

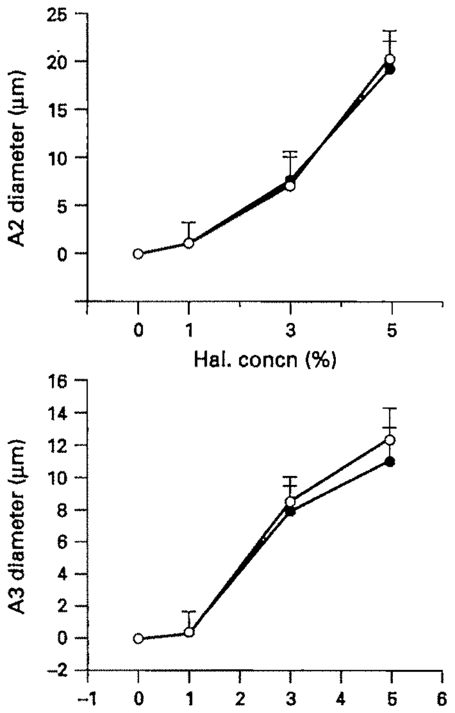

Figure 1 Increase in A2 (top) and A3 (bottom) diameter in response to 0–5 % halothane (Hal.) (mean, SD). First curve (●) = cumulative dose–response curve to administration of halothane (0, 1, 3 and 5 %) performed after a baseline measurement of arteriolar diameter. Second curve (○) = cumulative dose–response curve to administration of halothane performed after a 15-min wash-out period during which the muscle was irrigated with drug-free Krebs' solution. Halothane induced significant dose-dependent A2 and A3 dilatation ($P < 0.0001$) which was not different between the two dose–response curves.

EFFECTS OF HALOTHANE ON DIAPHRAGMATIC ARTERIOLAR DIAMETER

Halothane administered in concentrations of 0–5 % produced dose-dependent dilatation of diaphragmatic A2 and A3 arterioles (factor "dose" $P < 0.0001$ in both arteriolar orders). It must be noted, however, that in both arteriolar orders, dilatation was not observed until 3 % halothane was given (fig. 1).

The effect of halothane was completely reversible. When diaphragmatic muscle surface was washed after administration of halothane, A2 and A3 diameters were not different from baseline values (44.21 (6.50) µm and 25.71 (4.21) µm *vs* 46.12 (5.21) µm and 27.12 (3.85) µm, for A2 and A3, respectively). Furthermore, the dilatator capacity of the arterioles remained intact after halothane, as demonstrated by the similarity between the two dose–response curves to this agent performed with a 15-min washing period interval (fig. 1). Doses of halothane in Krebs' solution at the different concentrations used in this study are presented in table 1.

EFFECTS OF HALOTHANE IN THE PRESENCE OF LNA, MEFENAMIC ACID AND INDOMETHACIN

Baseline arteriolar diameters did not differ between the different groups of animals (table 2). LNA 300 µmol litre^{-1} mefenamic acid 20 µmol litre^{-1} and indomethacin 20 µmol litre^{-1} produced significant reduction in basal diaphragmatic arteriolar diameters (table 2). After LNA superfusion, A2 and A3 diameters were 85 (11) % ($P < 0.001$) and 84 (11) % ($P < 0.001$) of baseline values, respectively. After mefenamic acid superfusion, A2 and A3 diameters were 93 (3) % ($P < 0.001$) and 93 (6) % ($n = 32$; $P < 0.001$) of baseline values, respectively. After indomethacin superfusion, A2 and A3 diameters were 97 (5) % ($P < 0.05$) and 91 (4) % ($P < 0.001$) of baseline values, respectively. The reduction in diameter was related specifically to the inhibitors as superfusion of the diaphragm during a similar period with drug-free Krebs' solution did not result in any significant modification in arteriolar diameters (table 2).

Halothane-induced arteriolar dilatation was not modified by LNA (the interaction between "dose" and "absence or presence of inhibitor" was not significant for A2 and A3, when group C was compared with group LNA) (fig. 2). In contrast, halothane-induced increase in A2 and A3 diameters was almost totally inhibited by mefenamic acid

Table 1 Halothane doses (mg litre^{-1}) in Krebs' solution assessed by chromatography (mean (SD)). Number of samples for each concentration of halothane is seven. Halothane was not detected at a 0 % delivered concentration. The increase in the delivered concentration of halothane resulted in a significant increase in halothane concentration in Krebs' solution

Delivered concn	Dose (mg litre^{-1})
1 %	37.31 (7)
3 %	67.1 (8)
5 %	110.1 (1.2)

Table 2 Arteriolar diameters in the different groups of animals (mean (SD) and [number of arterioles studied]). LNA = $N\omega$-nitro-L-arginine; MA = mefenamic acid; INDO = indomethacin; C = control. No significant differences between the values at baseline. A significant reduction in diameter was observed after administration of LNA, MA and INDO (*$P < 0.05$)

	A2 (μm)		A3 (μm)	
Group	Baseline	After inhibitors	Baseline	After inhibitors
LNA	44.82 (5.91) [9]	38.36 (4.45)*	25.73 (4.98) [12]	21.71 (4.87)*
MA	49.13 (5.26) [10]	45.98 (5.36)*	29.32 (5.76) [12]	26.51 (5.63)*
INDO	44.08 (5.81) [9]	42.78 (5.71)*	24.91 (4.21) [9]	22.81 (3.82)*
C	44.63 (6.96) [9]	44.20 (6.80)	25.71 (6.08) [12]	25.20 (6.10)

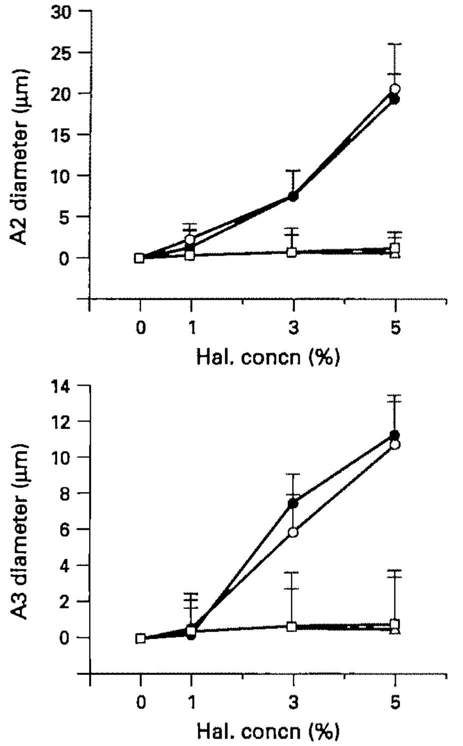

Figure 2 Increase in A2 (top) and A3 arteriole (bottom) diameter in response to 0–5 % halothane (Hal.) in the control group (●) ($n = 9$ and $n = 12$ arterioles for A2 and A3, respectively), group LNA receiving $N\omega$-nitro-L-arginine 300 μmol litre^{-1} (○) ($n = 9$ and $n = 12$ arterioles for A2 and A3, respectively), group MA receiving mefenamic acid 20 μmol litre^{-1} (△) ($n = 10$ and $n = 12$ arterioles for A2 and A3, respectively) and group INDO receiving indomethacin 20 μmol litre^{-1} (□) ($n = 9$ and $n = 9$ arterioles for A2 and A3, respectively) (mean, SD). Halothane induced significant dose-dependent A2 and A3 dilatation ($P < 0.0001$) which was not altered by administration of LNA but reduced significantly by mefanamic acid and indomethacin.

(interaction between factor "dose" and factor "absence or presence of inhibitor", $P < 0.0001$ for each arteriolar order, when group C was compared with group MA). A similar result was observed with indomethacin (interaction between factor "dose" and factor "absence or presence of inhibitor", $P < 0.0001$ for each arteriolar order, when group C was compared with group INDO).

Discussion

The main results of this study are that *in vivo*, topically administered halothane in a concentration range of 0–5 % produced dose-dependent dilatation of rat diaphragmatic arterioles and halothane-induced dilatation of diaphragmatic arterioles was abolished significantly by mefenamic acid and indomethacin, but not by LNA.

In this study, assessment of the role of nitric oxide and prostaglandins on the arteriolar responses of the diaphragm to halothane was performed indirectly using selective inhibitors of both pathways: LNA for nitric oxide and mefenamic acid and indomethacin for prostaglandins. A possible criticism of this design is that these agents may exert effects on diaphragmatic arterioles via mechanisms other than nitric oxide and prostaglandin synthesis inhibition, respectively. However, this is very unlikely. First, a large body of evidence has demonstrated that LNA is a potent and specific inhibitor of nitric oxide synthesis *in vitro* [7, 18] and *in vivo* in different vascular regions [19, 20], including diaphragmatic vessels [10, 21]. Furthermore, we demonstrated in a previous study that topically administered LNA, at the concentration used in this study, effectively blocked nitric oxide-mediated dilatation of diaphragmatic arterioles [10]. Second, we found an inhibitory effect of two structurally different inhibitors of prostaglandin synthesis: mefenamic acid and indomethacin [22]. Thus we are confident that the effects of these agents were related specifically to inhibition of the cyclo-oxygenase pathway.

The concentration of halothane in Krebs' solution perfusing the diaphragm is the determinant of its effect on diaphragmatic arterioles. Therefore, we ensured that the increasing concentrations of halothane resulted in increasing concentrations of this agent in Krebs' solution.

In this study halothane was administered topically, thus avoiding any significant effect of modification of arterial pressure. Consequently, the dilatation induced by this agent can be regarded as a direct relaxant effect on diaphragmatic arterioles. However, it must be noted that dilatation was observed only when halothane concentrations were greater than

1%. This is in line with previous *in vivo* data showing that inhalation of halothane at 0.5–1% failed to produce diaphragmatic A2 and A3 dilatation [4]. Furthermore, this confirms previous results of several *in vitro* studies showing that only halothane concentrations greater than 2% dilated KCl- or phenylephrine-precontracted rat aorta and canine carotid and coronary rings immersed in Krebs' solution [5, 23, 24]. Interestingly, Muldoon and co-workers [5] showed, in a canine femoral ring model, that 2% halothane bubbled in Krebs' solution induced significant contraction of these vessels. Although species differences could explain these controversial results, heterogeneity between the different vessels may also be involved. Absence of vasoconstriction of diaphragmatic arterioles during systemic [4] and topical administration of halothane may be related to the fact that properties of the diaphragmatic vessel may differ significantly from those of peripheral skeletal muscles [10].

Several mechanisms may explain diaphragmatic arteriolar dilatation induced by halothane. For example, it has been reported that halothane has a direct effect on smooth muscle calcium homeostasis and also causes endothelium-dependent relaxation [5]. In this study, we investigated this mechanism by assessing the role of two main vasodilator factors synthesized by the endothelium: nitric oxide and prostaglandins.

The absence of effect of LNA on halothane-induced A2 and A3 dilatation suggests that nitric oxide was not involved in the diaphragmatic arteriolar effects of halothane. In contrast, mefenamic acid and indomethacin induced complete inhibition of halothane-induced diaphragmatic arteriolar dilatation. As both agents increased arteriolar tone, suppression of halothane-induced dilatation may be related to this increase in smooth muscle vascular tone, which in turn may attenuate the relaxant effect of halothane. However, this possibility can be excluded as LNA, which induced a greater increase in arteriolar tone than mefenamic acid and indomethacin, did not modify the dilatation caused by halothane. In addition, complete inhibition of halothane-induced diaphragmatic A2 and A3 arteriolar dilatation by mefenamic acid and indomethacin demonstrated that the diaphragmatic arteriolar effect of halothane was mediated exclusively by prostaglandins. This result is in agreement with that reported by Stone and Johns [23] who showed that indomethacin attenuated the decrease in aortic ring tension observed with increasing doses of halothane. However, other effects of halothane, such as development of pulmonary vasoconstriction in dogs, are not mediated by prostaglandins [25]. It is interesting to note that prostaglandins contribute, together with nitric oxide, to modulation of diaphragmatic arteriolar tone [10], a phenomenon which has not been shown in other skeletal muscle microvessels [11, 12]. Thus it is possible to speculate that modulation of the prostaglandins pathway could be an important mechanism of action of pharmacological agents, such as halothane, in affecting the diaphragmatic microcirculation.

Ketamine inhibits nitric oxide production in mouse-activated macrophage-like cells

M. SHIMAOKA, T. IIDA, A. OHARA, N. TAENAKA, T. MASHIMO, T. HONDA AND I. YOSHIYA

Summary

We have investigated the effects of ketamine on nitric oxide produced by activated macrophages using a murine macrophage-like cell line, J774. Cells were incubated for 18 h under stimulation with lipopolysaccharide and interferon-γ or lipoteichoic acid and interferon-γ, with various concentrations of ketamine (6–600 μmol litre^{-1}). Nitric oxide production was assessed by measuring nitrite, a stable by-product of nitric oxide breakdown, in the medium. Other *N*-methyl-D-aspartate receptor antagonists, MK-801 (150 μmol litre^{-1}) and dextromethorphan (150 μmol litre^{-1}) were also tested. In addition, we studied the effects of ketamine on production of tumour necrosis factor-α by activated macrophages. Ketamine inhibited nitrite production dose-dependently with both lipopolysaccharide- and lipoteichoic acid-activated macrophages by up to approximately 65% at the highest ketamine concentration (600 μmol litre^{-1}). Neither MK-801 nor dextromethorphan had an inhibitory effect. Ketamine also suppressed production of tumour necrosis factor-α. The data show that ketamine inhibited nitric oxide production by activated macrophages probably, in part, via inhibition of production of tumour necrosis factor-α, an autocrine stimulatory factor for nitric oxide production, but not via the NMDA receptor pathway, which is involved in neuronal nitric oxide production. (*Br. J. Anaesth.* 1996; **77**: 238–242)

Nitric oxide is a short-lived radical produced by enzymatic oxidation of L-arginine. At least two distinct forms of nitric oxide synthase have been reported; constitutive and inducible [1, 2]. Constitutive nitric oxide synthase is distributed in the vascular endothelium and in the brain [1, 2]. Nitric oxide produced by constitutive nitric oxide synthase in the endothelium acts as a vasodilator and nitric oxide produced by constitutive nitric oxide synthase in the brain acts as a neurotransmitter. Inducible nitric oxide synthase is found in activated macrophages and in various types of cells. Activated macrophages produce large amounts of nitric oxide, which is considered an essential mediator in host defence because of its cytotoxic effects on tumour cells and micro-organisms [1, 2]. The cytotoxic effect of nitric oxide derived from activated macrophages is so strong that not only target cells but also normal surrounding cells may be damaged. Recent investigations have shown that nitric oxide from activated macrophages is involved in the pathogenesis of various types of diseases, such as septic shock [3], diabetes mellitus [4], reperfusion injury [5] and ischaemic neuronal damage [6]. In ischaemic neuronal damage, glutamate is thought to play a pivotal role via the subsequent activation of *N*-methyl-D-aspartate (NMDA) receptors [7]. Recently, not only glutamate but also nitric oxide produced by the brain macrophage, microglia, has been reported to be involved in the pathogenesis of neuronal damage [8]. Ketamine, a dissociative general anaesthetic, blocks excitation involving NMDA receptors and acts as a noncompetitive NMDA receptor antagonist. Ketamine and other NMDA receptor antagonists have been shown to reduce ischaemia- or NMDA-induced neuronal damage [9, 10]. Evidence has subsequently appeared suggesting that MK-801, a NMDA receptor antagonist, and ketamine, inhibit nitric oxide produced by constitutive nitric oxide synthase in cultured cerebral neurones [11].

In this study we have investigated the effect of ketamine on nitric oxide production from inducible nitric oxide synthase in activated macrophages and speculate on the possibility of ketamine offering protection against nitric oxide-mediated tissue injury, such as neurotoxicity in hypoxic cerebral damage and microvascular injury in septic shock.

Materials and methods

CHEMICALS

Chemicals used in this study were obtained from the following sources: ketamine hydrochloride, lipopolysaccharide, lipoteichoic acid, mouse interferon-γ,

dextromethorphan, dexamethasone and fetal calf serum (FCS) from Sigma (St Louis, MO, USA); MK-801 from Research Biochemicals International (Natick, MA, USA); RPMI 1640 medium containing kanamycin 50 µg ml^{-1} from the Research Foundation for Microbial Diseases of Osaka University (Osaka, Japan); sulphanilamide, naphthylethylene diamine dihydrochloride, H_3PO_4, $NaNO_2$ from Wako Pure Chemical Industries, Ltd (Osaka, Japan).

CELL CULTURE

The mouse macrophage-like cell line, J774, derived from the tumour of a female BALB/c mouse, has been shown to possess characteristics typical of macrophages, including phagocytic properties and the ability to produce pro-inflammatory cytokines and nitric oxide [12]. This cell line was kindly provided by the Japanese Cancer Research Resources Bank. J774 cells were maintained in RPMI 1640 medium supplemented with 10 % fetal calf serum and kanamycin 50 µg ml^{-1} at 37 °C in an atmosphere of 5 % carbon dioxide. Cells were plated in 48-well culture plates at a density of 10^6 ml^{-1} and allowed to adhere for 2 h; the medium was then replaced with fresh medium containing varying amounts of reagents. After 18 h of incubation, supernatants were harvested to determine nitrite, tumour necrosis factor-α and lactate dehydrogenase release and the cells were subjected to viability assay using trypan blue.

NITRITE MEASUREMENT

The amount of nitric oxide released during incubation was determined by measuring nitrite, a stable by-product of nitric oxide breakdown. Nitrite measurement is widely accepted as a means of evaluating nitric oxide production indirectly *in vitro* [13–15] and *in vivo* [16, 17]. Nitrite in culture supernatant was assayed by Griess reaction, as described previously [18]. Briefly, 100 µl of medium was incubated with 100 µl of Griess reagent (1 % sulphanilamide, 0.1 % naphthylethylene diamine dihydrochloride and 2 % H_3PO_4) for 10 min at room temperature, and then the absorbance at 550 nm was measured. Nitrogen dioxide concentration was determined using $NaNO_2$ as a standard.

TNF ASSAY

Secretion of tumour necrosis factor-α was determined by enzyme-linked immunosorbent assay (ELISA) using a mouse tumour necrosis factor-α ELISA kit (Endogen, Inc., Cambridge, MA, USA).

CELL VIABILITY

To confirm that ketamine in the concentrations used in this study had no cytotoxic effect on J774 cells, cell viability was determined both by trypan blue exclusion assay and by measuring the amount of lactate dehydrogenase released into the medium, a well-characterized indicator of toxicity, with a commercial kit (lactate dehydrogenase cytotoxicity test; Wako Pure Chemical Industries Ltd, Osaka, Japan). Cell viability was assessed by comparing the percentage of cells which were not stained by trypan blue with PBS-treated cells (a negative control); lactate dehydrogenase release was expressed as a percentage of the total amount of lactate dehydrogenase present in the cells, which was determined by measuring Triton X-treated cell lysate.

Cell viability determined by trypan blue staining was more than 95 % in all groups. Ketamine, even at the highest concentration used in this study (600 µmol litre^{-1}), did not release lactate dehydrogenase; ketamine 600-µmol litre^{-1} samples released 18.3 (0.2) % and control samples released 18.3 (0.6) % of total lactate dehydrogenase (Triton-X lysate).

DATA ANALYSIS

All values were derived from more than three independent experiments. Data were expressed as mean (SEM) and differences between values were analysed using the Mann–Whitney *U* test or ANOVA; when $P < 0.05$, differences were considered significant.

Results

NITRITE PRODUCTION BY MACROPHAGES ACTIVATED BY LIPOPOLYSACCHARIDE AND INTERFERON-γ OR LIPOTEICHOIC ACID AND INTERFERON-γ

Both lipoteichoic acid, a component of the cell walls of gram-positive bacteria, and lipopolysaccharide, which is part of the cell walls of gram-negative bacteria, are known to induce macrophages to produce nitric oxide [19]. Interferon-γ enhances this nitric oxide production. As shown in table 1, lipopolysaccharide 10 ng ml^{-1} or lipoteichoic acid 5 µg ml^{-1} induced nitrite production by macrophages, when treated with interferon-γ 100 u. ml^{-1}.

EFFECTS OF KETAMINE ON NITRITE PRODUCTION BY MACROPHAGES

Various concentrations of ketamine (6–600 µmol litre^{-1}) were added to the macrophage culture samples concurrently with lipopolysaccharide or lipoteichoic acid stimuli. As shown in figure 1, ketamine suppressed nitric oxide production dose-dependently, evaluated as nitrite accumulation, at concentrations of 30–600 µmol litre^{-1} in macrophages activated by lipopolysaccharide and interferon-γ at concentration of 15–600 µmol litre^{-1} in samples activated by lipoteichoic acid and interferon-γ. The IC_{50} for lipopolysaccharide- and

Table 1 Nitrite production by activated macrophages (mean (SEM)). J774 cells were incubated with various types of stimuli for 18 h and the amount of nitrite production was determined by Griess reaction. LPS = Lipopolysaccharide, IFNγ = interferon-γ and LTA = lipoteichoic acid

Stimulus	Nitrite (µmol litre^{-1})
LPS (10 ng ml^{-1})+IFNγ (100 u. ml^{-1})	37.9 (0.8)
LTA (5 µg ml^{-1})+IFNγ (100 u. ml^{-1})	42.7 (1.1)
None	0.4 (0.1)

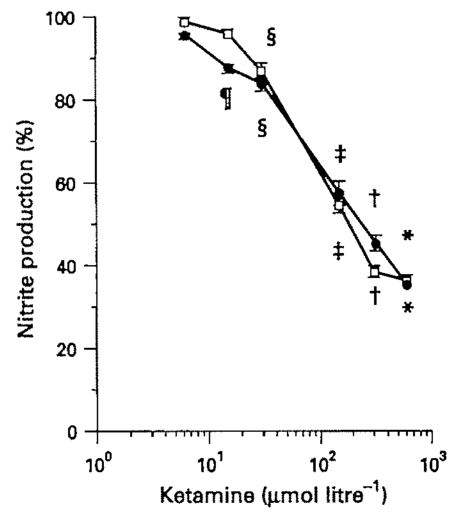

Figure 1 Inhibition by ketamine of nitrite production by macrophages activated by lipopolysaccharide 10 ng ml^{-1} and interferon-γ 100 u. ml^{-1} (□) or lipoteichoic acid 5 µg ml^{-1} and interferon-γ 100 u. ml^{-1} (●). J774 cells were incubated for 18 h under stimulation with lipopolysaccharide and interferon-γ or lipoteichoic acid and interferon-γ, with various amounts of ketamine (6–600 µmol $litre^{-1}$). Nitric oxide production was determined by measuring nitrite in the medium. Values are expressed as mean (SEM) percentage of control (containing no ketamine). Ketamine inhibited nitric oxide production by macrophages dose-dependently. The IC_{50} values for lipopolysaccharide- and interferon-γ- and lipoteichoic acid- and interferon-γ-induced nitric oxide production by macrophages were 281 and 266 µmol $litre^{-1}$, respectively. $*P < 0.05$ *vs* 300, 150, 60, 30, 6 and 0 µmol $litre^{-1}$; $\dagger P < 0.05$ *vs* 150, 60, 30, 6 and 0 µmol $litre^{-1}$; $\ddagger P < 0.05$ *vs* 60, 30, 6 and 0 µmol $litre^{-1}$; $\S P < 0.05$ *vs* 30, 6 and 0 µmol $litre^{-1}$; $\P P < 0.05$ *vs* 6 and 0 µmol $litre^{-1}$.

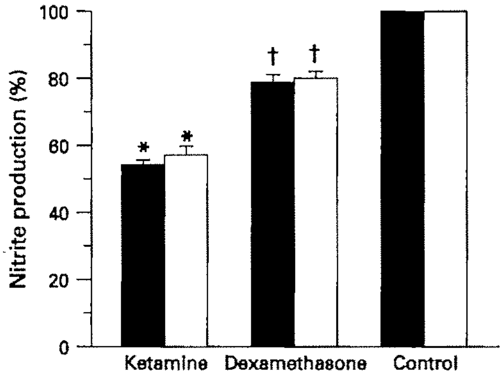

Figure 2 Comparison of the effects of ketamine 150 µmol $litre^{-1}$ and dexamethasone 150 µmol $litre^{-1}$, a well-known inhibitor of inducible nitric oxide synthase induction, on nitrite production by macrophages activated by lipopolysaccharide 10 ng ml^{-1} and interferon-γ 100 u. ml^{-1} (■) or lipoteichoic acid 5 µg ml^{-1} and interferon−γ 100 u. ml^{-1} (□). The inhibitory effect of ketamine was stronger than that of dexamethasone at the same concentration. Values are expressed as mean (SEM) percentages of control (stimuli only). $*P < 0.05$ *vs* dexamethasone and control; $\dagger P < 0.05$ *vs* control.

interferon-γ-induced nitrite production by macrophages was 281 µmol $litre^{-1}$, and 266 µmol $litre^{-1}$ for lipoteichoic acid- and interferon-γ-induced nitrite production. The extent of inhibition of nitrite production by ketamine 150 µmol $litre^{-1}$ was stronger than that of dexamethasone 150 µmol $litre^{-1}$, which is a well-known inhibitor of nitric oxide production by activated macrophages [20] (fig. 2).

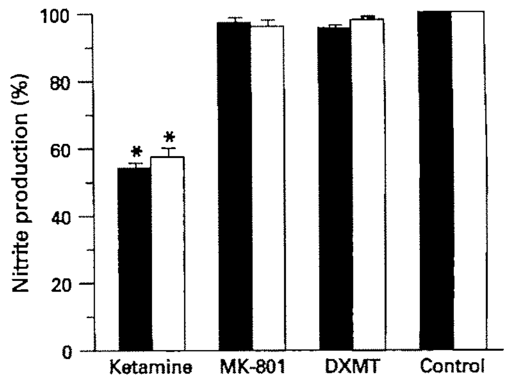

Figure 3 Comparison of the effects of ketamine 150 µmol $litre^{-1}$ and other NMDA receptor antagonists on nitrite production by macrophages activated by lipopolysaccharide 10 ng ml^{-1} and interferon-γ 100 u. ml^{-1} (■) or lipoteichoic acid 5 µg ml^{-1} and interferon-γ 100 u. ml^{-1} (□). MK-801 150 µmol $litre^{-1}$ and dextrometrophan (DXMT) 150 µmol $litre^{-1}$, both potent NMDA receptor antagonists, failed to inhibit nitric oxide production. Values are expressed as mean (SEM) percentages of control (stimuli only). $*P < 0.05$ *vs* control.

EFFECTS OF OTHER NON-COMPETITIVE NMDA RECEPTOR ANTAGONISTS ON NITRITE PRODUCTION BY ACTIVATED MACROPHAGES

In order to investigate if NMDA receptor pathways are involved in the inhibitory effect of ketamine on nitrite production, we tested the effects of two potent non-competitive NMDA receptor antagonists, MK-801 and dextromethorphan. In contrast with ketamine, neither MK-801 150 µmol $litre^{-1}$ nor dextromethorphan 150 µmol $litre^{-1}$ inhibited nitrite production in lipopolysaccharide- and lipoteichoic acid-activated macrophages (fig. 3). Similar doses of these antagonists have been reported to be adequate to block the NMDA receptor channels of neuronal cells [11, 21, 22].

EFFECTS OF KETAMINE ON TNF PRODUCTION BY ACTIVATED MACROPHAGES

Tumour necrosis factor-α is a pro-inflammatory cytokine released from activated macrophages and a key mediator in septic shock [23]. Because the endogenous production of tumour necrosis factor-α has been reported to stimulate nitric oxide production in the autocrine system [24], we examined the effects of ketamine on production of tumour necrosis factor-α.

As shown in table 2, ketamine suppressed production of tumour necrosis factor-α by lipopolysaccharide- and lipoteichoic acid-activated macrophages dose-dependently.

Discussion

Although the extent of influence of anaesthetics on host defence and the immune system is largely unknown, some of the immunosuppressive effects of anaesthetic agents *in vitro* have been reported [25, 26]. Under normal conditions, the immune system provides essential protection for the host, but if the immune system is overactivated or improperly activated, it becomes excessively cytotoxic and can

Table 2 Inhibition by ketamine of tumour necrosis factor-α (TNF-α) production from macrophages activated by lipopolysaccharide (LPS) and interferon-γ (IFNγ) or lipoteichoic acid (LTA) and IFNγ. J774 cells were incubated for 18 h under stimulation with LPS and IFNγ or LTA and IFNγ with various amount of ketamine. The amount of TNF-α production was determined by ELISA. Values are expressed as mean (SEM) percentages of control (no ketamine, stimuli only). $^*P < 0.05$ *vs* control; $^\dagger P < 0.05$ *vs* 10 $\mu g\ ml^{-1}$ and control

Concentration of ketamine ($\mu mol\ litre^{-1}$)	% Production of TNF-α

damage normal tissues, typically seen in sepsis [27], ARDS [28], autoimmune diseases [29] and ischaemic brain injury [30]. In this regard, further investigation of the immunosuppressive effects of anaesthetic agents may lead to new strategies in treating disorders related to overactivation of the immune system. Nitric oxide is implicated in the injury of tissues in various organs [1, 2]; in this study we focused on nitric oxide produced by inducible nitric oxide synthase in activated macrophages, and showed that ketamine inhibited nitric oxide production dose-dependently.

Recently the role of nitric oxide endogenously generated by inducible nitric oxide synthase in the physiology and pathophysiology of organs has been better appreciated and the mechanisms which may regulate nitric oxide production have been investigated. The list of factors shown to inhibit nitric oxide production continues to grow: corticosteroid [19], transforming growth factor-β [13], interleukin-4 [14], interleukin-10 [24], macrophage deactivating factor [31] and macrophage-stimulating protein [15] have been reported to inhibit the induction of nitric oxide production by macrophages stimulated by lipopolysaccharide or cytokines. We found the inhibitory effect of ketamine 150 $\mu mol\ litre^{-1}$ was stronger than that of dexamethasone 150 $\mu mol\ litre^{-1}$. Because we still do not know how ketamine inhibits nitric oxide production by macrophages, we also examined the involvement of NMDA receptors. Activation of NMDA receptors in the central nerve system results in nitric oxide synthesis by constitutive nitric oxide synthase in neuronal cells [32]. Another study showed that ketamine and other non-competitive NMDA receptor antagonists inhibited nitric oxide production in cultured cerebral neurones [11].

Although an NMDA receptor has yet to be identified in macrophages, we tested the effects of MK-801 and dextromethorphan on the production of nitric oxide by activated macrophages and found no inhibition. These results indicate that whether or not macrophages possess NMDA receptors, involvement of NMDA receptors in the inhibition of nitric oxide production by ketamine would still seem unlikely.

Ketamine inhibited production of tumour necrosis factor-α dose-dependently, a finding consistent with a previous report [26]. This suggests that inhibition of nitric oxide production by ketamine may be caused partially by inhibition of endogenous production of tumour necrosis factor-α.

The presence of activated macrophages at sites of neurone damage, observed in brain injury and degenerative brain, has lead to the suggestion that the cytotoxicity of macrophages is responsible for the damage [33]. Recent experiments have provided further evidence that macrophages are responsible for neuronal damage; reduction in the recruitment of macrophages, achieved by body irradiation or by macrophage inactivation with colchicine, which inhibits the assembly of microtubules and suppresses the phagocytic and secretory functions, reduces cell death in ischaemic injury or ibotenic acid-induced brain damage [30, 34]. Nitric oxide released by activated macrophages has also been found to be cytotoxic to neurones [10]. The ability of ketamine to act against neuronal damage may thus be expected not only to derive from inhibition of the NMDA receptor in neurones [35, 36] but also partially from inhibition of nitric oxide production by macrophages in the brain.

In septic shock, or systemic inflammatory response syndrome (SIRS), tumour necrosis factor-α released from macrophages plays a pivotal role in pathogenesis [23]. Tumour necrosis factor-α alone, however, cannot explain the complex pathophysiological alternation in SIRS. There has been speculation concerning the participation of alternative mediators, including other cytokines and nitric oxide [37]. In this context, ketamine may prove worthy of consideration in a new form of therapy because, *in vitro*, it inhibits both tumour necrosis factor-α and nitric oxide production by macrophages. Reported serum concentration of ketamine used in anaesthetic doses, however, are less than 80 $\mu mol\ litre^{-1}$ in animals [38, 39] and less than 7 $\mu mol\ litre^{-1}$ in humans [40, 41]. The latter is small compared with the effective values in this study. If higher doses of ketamine were administered, the inhibitory effects found in this study may be clinically significant. Further investigation is needed to determine the possible therapeutic uses of ketamine.

Potentiation of local lignocaine-induced sensory block by calcium channel blockers in rats

H. IWASAKI, H. OHMORI, K. OMOTE, M. KAWAMATA, S. SUMITA, M. YAMAUCHI AND A. NAMIKI

Summary

We have studied the effects of three different types of calcium channel blockers (verapamil, diltiazem, and nicardipine) on local lignocaine sensory block. The standardized tail flick test was used to measure the duration and degree of lignocaine-induced conduction block in rats. After obtaining baseline tail flick latencies (mean 3.2 s), two 100-µl doses of 0.3% lignocaine alone, a combination of verapamil 25, 100 or 200 µg, diltiazem 25, 100 or 200 µg, or nicardipine 0.5, 1.0 or 2.0 µg, and a large dose of calcium channel blockers (verapamil 200 µg, diltiazem 200 µg or nicardipine 2.0 µg) were injected on opposite sites of the tail base and the tail flick test was performed every 5 min for 45 min. A large dose of the calcium channel blockers showed no prolongation of tail flick latencies. Administration of 0.3% lignocaine alone produced a significant increase in tail flick thresholds and the peak effect of the percentage maximum possible effect (%MPE) was demonstrated at 5 min after drug injection (mean %MPE 28.8%; $P < 0.01$ *vs* baseline). Co-administration of 0.3% lignocaine and three doses of verapamil produced significant increases in area under the curve (AUC) in a dose-dependent fashion. Mean AUC values for 0.3% lignocaine alone and a combination of verapamil 25, 100 or 200 µg were 217.5, 502.5, 529.1 and 1600.3, respectively. Almost similar patterns of augmentation in AUC values were demonstrated after addition of different doses of diltiazem or nicardipine to 0.3% lignocaine. We conclude that the use of mixtures of local anaesthetic and calcium channel blocker potentiated lignocaine sensory block at the level of the peripheral nerves. (*Br. J. Anaesth.* 1996; **77**: 243–247).

Key words

Anaesthetics local, lignocaine. Calcium channel block, verapamil. Calcium channel block, diltiazem. Calcium channel block, nicardipine. Rat.

The primary action of local anaesthetics reversibly blocks conduction of nerve impulses by preventing increases in the permeability of the nerve membrane to sodium ions. Calcium movement is essential for normal sensory processing and plays a role in axonal conduction and synaptic transmission. Recently it has been reported that local anaesthetics depress influx of calcium ions at concentrations required to block nerve conduction [1, 2].

Calcium channel blockers block sodium in addition to calcium channels [3] and have local anaesthetic actions [4, 5]. Interaction between calcium channel blockers and local anaesthetic agents is now well documented [6, 7]. We have also reported that intrathecally administered verapamil potentiated the depth and duration of spinal anaesthesia with lignocaine [8]. Therefore, we hypothesized that co-administration of calcium channel blocking agents would increase the analgesic effects of local anaesthetics.

In this study we examined if calcium channel blockers could potentiate and prolong sensory block with lignocaine at peripheral nerves in rats.

Materials and methods

The study was approved by our Animal Care and Use Committee. Male Sprague–Dawley rats, weighing 250–300 g, were used in the experiments. Animals were housed in a temperature-controlled (21 ± 1 °C) room with a 21-h light-dark cycle (lights on 07:00 to 19:00) and given free access to food and water. To reduce the effects of handling on nociceptive responses, all animals were handled and trained in the test situation for at least 3 days before testing. A maximum of three experiments was conducted on each rat with a minimum of 3 days between studies.

NOCICEPTIVE TEST

To assess the thermal nociceptive threshold, the standardized tail flick test was performed, using a restrain box, by monitoring latency to withdraw from a heat source (a 50-W projection lamp bulb) focused on a distal segment of the tail (KN-205E, Natume, Japan). A single control switch simultaneously activated the light and a timer. The time interval between switching on the light to flick of the tail was recorded as tail flick latency. The location on the tail stimulated was varied systematically so that

Correspondence to H.I.

the same portion of the tail was not exposed repeatedly to the light source. A 10-s cut-off time was used in the tail flick tests to minimize tissue damage. Mean baseline tail flick latency was 3.2 (2.8–3.9) s in the experiment.

DRUGS AND INJECTION

The drugs used were lignocaine hydrochloride (Fujisawa, Osaka, Japan), verapamil hydrochloride (MW 491.07; Sigma, St Louis, MO, USA), diltiazem hydrochloride (MW 450.99; Tanabe, Osaka, Japan) and nicardipine hydrochloride (MW 515.99; Yamanouchi, Tokyo, Japan). Drugs were freshly dissolved in sterile physiological saline in concentrations that allowed local injection at the root of the tail in 100- μl volumes. Animals were placed in individual plastic cylinders with an opening to allow the tail to protrude. After determining baseline tail flick latencies, 0.3 % lignocaine alone, or combined with verapamil 25, 100 or 200 μg, diltiazem 25, 100 or 200 μg, or nicardipine 0.5, 1.0 or 2.0 μg, and verapamil 200 μg, diltiazem 200 μg or nicardipine 2.0 μg alone were injected bilaterally at the base of the tail in 200-μl volumes, in a randomized manner. Using the modified methods of Grant and colleagues [9], two 100-μl of volumes of each drugs were injected directly into the base of the animal's tail on opposite sides of the midline using a 30-gauge needle attached to a 100-μl syringe (Hamilton, Reno, NV, USA). Accurate bilateral injections were noted to result in slight circumferential swelling of the tail root, as described in an original report. Tail flick latencies were evaluated 5, 10, 15, 20, 30 and 45 min after administration of the drug at the root of the tail.

The pH values of the solutions of 0.3 % lignocaine, calcium channel blockers and mixtures of 0.3 % lignocaine and calcium channel blocker in physiological saline were analysed by an ABL3 (Radiometer, Copenhagen, Denmark). The pH of a 100-μl solution of verapamil, 200 μg, diltiazem 200 μg, nicardipine 2.0 μg, 0.3 % lignocaine–200 μg verapamil, 0.3 % lignocaine–200 μg diltiazem, and 0.3 % lignocaine–2.0 μg nicardipine were 5.81, 5.37, 5.28, 6.25, 6.01 and 5.59, respectively.

CARDIOVASCULAR VARIABLES AND TAIL TEMPERATURE

To examine cardiovascular variables and temperature in the tail, arterial pressure, heart rate and skin temperature at the middle of the tail were measured before and after administration of 0.3 % lignocaine–200 μg verapamil in the four animals in which an arterial catheter had been inserted via the internal carotid artery.

STATISTICAL ANALYSIS

The response for the tail flick test was calculated as percentage maximum possible effects (%MPE): %MPE = (post-drug latency − baseline latency)/(cut-off time − baseline latency) × 100 %. The area under the curve (AUC) of %MPE *vs* time was calculated using the trapezoidal rule in order to express the overall magnitude and duration of effect for the tail flick test. Differences in %MPE and AUC between groups, and within-group differences between baseline values and those after administration of the drugs, were tested using Friedman's analysis of variance (ANOVA) by ranks and the Mann-Whitney *U* test. $P < 0.05$ was considered statistically significant. All data are expressed as mean (SEM).

Results

Animals were able to move their tail at random throughout the experiments. Lignocaine 0.3 % alone, administered at the base of the tail, produced

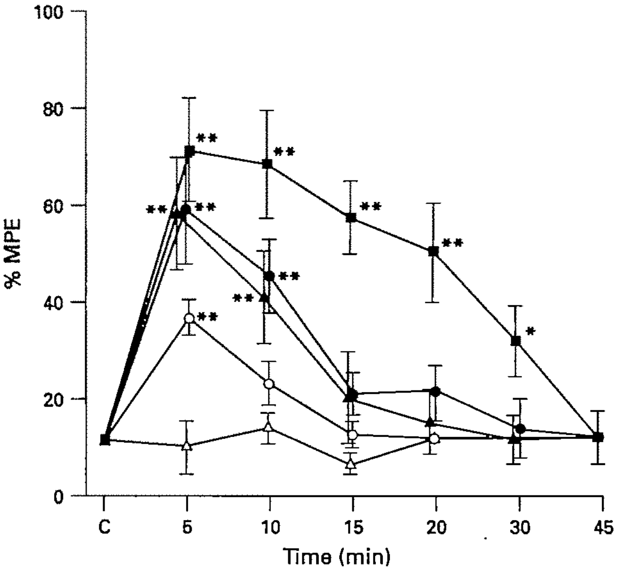

Figure 1 Changes in percentage maximum possible effect (% MPE) after injection of 0.3 % lignocaine (○, $n = 8$), verapamil 200 μg (△, $n = 5$) and a mixture of 0.3 % lignocaine and verapamil 200 μg (■, $n = 8$), 100 μg (●, $n = 6$) or 25 μg (▲, $n = 6$). Figure 3 Changes in percentage maximum possible effect (% MPE) after injection of 0.3 % lignocaine (○, $n = 8$), nicardipine 2.0 µg (△, $n = 5$) and a mixture of 0.3 % lignocaine and nicardipine 2.0 µg (■, $n = 7$), 1.0 µg (●, $n = 5$) or 0.5 µg (▲, $n = 5$). Data are mean, SEM. *$P < 0.05$, **$P < 0.01$ compared with control (C) (pre-injection) value.

significant prolongation of tail flick latency. The peak effect was observed 5 min after drug administration. A large dose of calcium channel blocker (verapamil 200 µg, diltiazem 200 µg or nicardipine 2.0 µg) alone did not produce prolongation of tail flick latency compared with each pre-drug value.

In contrast, co-administration of lignocaine and the three different doses of verapamil produced a dose-dependent increase in tail flick latencies and the duration of sensory block increased with increasing concentration of verapamil compared with lignocaine alone (fig. 1).

A similar pattern of augmentation in % MPE and AUC after addition of different doses of diltiazem or nicardipine to 0.3 % lignocaine resulted in an increase in % MPE and AUC, which were approximately dose-dependent increases in the tail flick test (figs. 2–4).

There were no significant changes in mean arterial pressure, heart rate or tail temperature after local injection of the drugs at the base of the tail (data not shown).

Discussion

We have demonstrated that local sensory block of lignocaine was potentiated and prolonged by concomitantly administered L-type calcium channel blockers (which alone exert no influence on local sensory block) in a dose- and time-related manner.

Local anaesthetics such as lignocaine, procaine, amylocaine or cinchocaine have been shown to inhibit calcium uptake and the calcium ion-activated ATPase activity of sarcoplasmic reticulum vesicles [10–12]. This ability of local anaesthetic agents to inhibit calcium efflux from the sarcoplasmic reticulum was explained by incorporation of these amphophilic drugs into the lipid layer [13, 14], interaction with calcium ion binding sites on membrane phospholipids, or direct interaction with a calcium channel [15, 16].

Calcium channel blockers block sodium channels in addition to calcium channels in a dose-dependent manner and have local anaesthetic actions. Kraynack, Lawson and Gintautas demonstrated that a blocking action of the fast sodium channel by verapamil was almost equal to that of procaine, although the mode of pharmacological action of these drugs was different. It has also been demonstrated that simultaneous administration of an amide local anaesthetic agent and the calcium channel blocker, verapamil, has more marked cardiovascular depressant effect than local anaesthetic alone [6, 7]. In this study, a large dose of calcium channel blocker alone, administered into the base of the tail, produced no significant antinociceptive effects. It is therefore

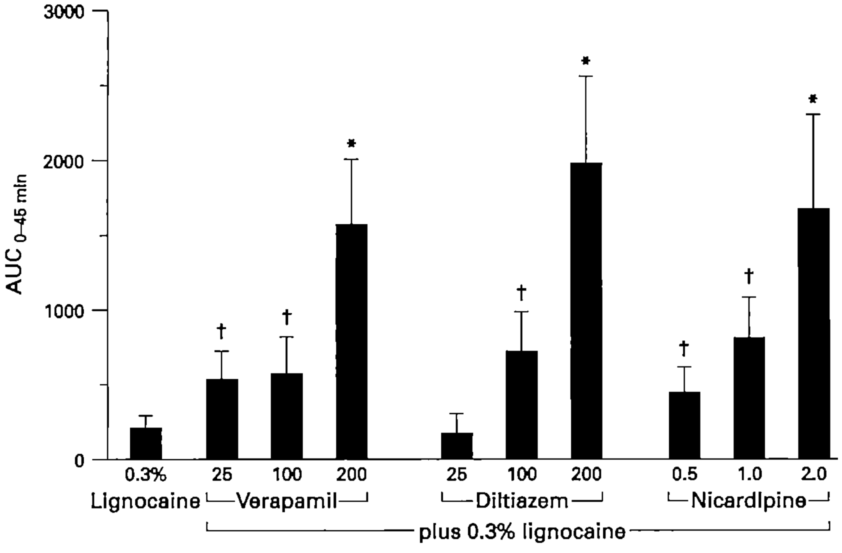

Figure 4 Area under the curve (AUC) of % MPE × time (0–45 min) after injection of 0.3 % lignocaine alone, and combined with verapamil 25, 100 or 200 µg, diltiazem 25, 100 or 200 µg or nicardipine 0.5, 1.0 or 2.0 µg. Data are mean, SEM. * $P < 0.05$, **$P < 0.01$ compared with 0.3 % lignocaine alone.

unlikely that the local anaesthetic activity of calcium channel blocking agents accounts for the increase in tail flick latency observed in the study, although little is known of the specific mechanism of augmentation of lignocaine sensory block by calcium channel blockers.

Several investigators have used *in vivo* animal models to evaluate local anaesthetic-induced conduction block. However, some of these studies have assessed sensory loss using non-quantitative methods. Analgesia tests in the rat using thermal stimulation such as tail flick or hot plate have been used for many years. These tests are useful for evaluation of systemic or neuroaxial analgesics but have limited use for local anaesthetics because they cannot clearly differentiate between motor and sensory block. A recent report has indicated that local anaesthetic injection directly into the base of the tail is a simple and reliable *in vivo* laboratory method using the standard tail flick test for comparing sensory block produced by different local anaesthetics [9]. These injections produce no motor block as tail motion is controlled by ligaments originating in muscles proximal to the level of the injection sites. Thus, the model enabled us to assess independently local sensory block produced by the injected drugs. In our study, all animals were able to move their tail at random after injection of the drugs.

It has been known widely that systemic administration of calcium channel blocker causes vasodilatation and cardiac depression, which result in hypotension and bradycardia [17]. No significant circulatory changes were observed in that study. Another possibility that could explain the observed effects would be a pharmacokinetic interaction between the drug solutions, such as changes in the pH of the tissue of the injection sites. Concomitant administration of lignocaine and calcium channel blockers might produce pharmacodynamic changes in tail temperature or regional blood flow. It is also not enough to explain the fact that local lignocaine sensory block was potentiated by co-administration of calcium channel blockers because administration of a large dose of calcium channel blockers alone did not produce a significant change in tail flick latency, as described above.

In this study we used three different calcium channel blockers with different structures: diphenylalkylamine (verapamil), benzothiazepine (diltiazem) and dihydropyridine (nicardipine). ID_{50} values for maximum amplitude of the calcium ion inward current in ileum smooth muscle of rabbits have been reported as 1.4 μmol litre^{-1}, 1.3 μmol litre^{-1} and 24 nmol litre^{-1} for verapamil, diltiazem and nicardipine, respectively [18]. Although the doses of calcium channel blockers co-administered in the study may not be exactly equipotent on neuronal calcium channels, similar patterns of augmentation of local sensory block of lignocaine by the three different structures of calcium channel blockers were demonstrated. These results suggest that the potentiation observed in the study was probably caused by direct inhibition of voltage-dependent calcium conductance, and consequent lowering of calcium ions of the peripheral nerves.

In conclusion, we have demonstrated that co-administration of a calcium channel blocker potentiated the degree and duration of local lignocaine sensory block. Most local anaesthetic drugs can be used for peripheral nerve block and the choice of drug is determined primarily by the required duration of anaesthesia. The duration of sensory analgesia is prolonged significantly when vasoconstrictors, usually adrenaline, are frequently added to local anaesthetic solutions. However, addition of a vasoconstrictor may cause cardiovascular disturbances, including cardiac arrhythmia or hypertension. The use of mixtures of local anaesthetic and calcium channel blocker may offer clinical advantages, with peripheral nerve block for chronic pain management. However, more study is required before co-administration of lignocaine and calcium channel blockers can be considered for clinical use.

I.v. anaesthetic agents inhibit dihydropyridine binding to L-type voltage-sensitive Ca^{2+} channels in rat cerebrocortical membranes†

K. HIROTA AND D. G. LAMBERT

Summary

Previous studies have implicated the neuronal L-type voltage-sensitive Ca^{2+} channel (VSCC) as a target site for i.v. anaesthetic agents. It is unclear if these agents interact with the L-channel α-subunit 1,4-dihydropyridine (DHP) binding site. In this study, we have examined the interaction of thiopentone, pentobarbitone, ketamine, etomidate, propofol and alphaxalone, and the non-anaesthetic barbiturate, barbituric acid, with the DHP binding site on rat cerebrocortical membranes. Binding assays were performed in 1-ml volumes of Tris-HCl 50 mmol litre^{-1}, pH 7.4, for 90 min at room temperature containing 200 μg of membrane protein with [^{3}H]PN200-110 as a radiolabelled DHP. Non-specific binding was defined in the presence of nifedipine 10^{-6} mol litre^{-1}. The interaction of i.v. anaesthetics was determined by displacement of [^{3}H]PN200-110 0.2 nmol litre^{-1}. All i.v. anaesthetics showed some interaction with the DHP binding site. The concentrations of anaesthetic producing 25% inhibition of specific binding (corrected for the competing mass of [^{3}H]PN200-110), K_{25} were (μmol litre^{-1}): thiopentone 48 (SEM 2), pentobarbitone 95 (7), propofol 40 (2), etomidate 25 (2), alphaxalone 17 (3) and ketamine 198 (16). Barbituric acid was ineffective. With the exception of ketamine, there was a significant correlation between K_{25} and peak serum concentration during anaesthesia ($P = 0.033$) and serum concentrations on wakening ($P = 0.018$), suggesting that the L-channel DHP binding site may be a target for i.v. anaesthetic agents. (*Br. J. Anaesth.* 1996; **77**: 248–253)

Key words

Anaesthetics i.v. Ions, ion channels. Ions, calcium. Model, rat.

Neuronal L-type voltage-sensitive Ca^{2+} channels are located predominantly on neuronal cell bodies and are involved in the regulation of neurotransmitter release [1]. Moreover, L-type Ca^{2+} channel blockers potentiate anaesthetic potency *in vivo* [2–6]. These findings suggest that L-type voltage-sensitive Ca^{2+} channels may be a target site for general anaesthetic agents. Indeed, i.v. anaesthetics are known to interact with 1,4-dihydropyridine (DHP) binding sites on L-type Ca^{2+} channels in skeletal [7] and smooth muscle [8], and there is evidence to suggest that i.v. anaesthetics inhibit neuronal L-type Ca^{2+} channels [9, 10]. It is still unclear, however, if i.v. anaesthetic agents interact directly with DHP binding sites on the α_1 subunit of neuronal L-type Ca^{2+} channels. In contrast, the interaction of volatile general anaesthetic agents is well documented [11, 12]. In this study, we examined if a range of i.v. anaesthetic agents interact with the DHP binding site (labelled with (+)-[methyl-^{3}H]PN200-110, (+)-[methyl-^{3}H]isopropyl-4-(2,1,3-benzoadiazol-4-yl)-1,4-dihydro-5-methoxycarbonyl-2,6-dimethyl-3-pyridinecarboxylate) on neuronal L-type Ca^{2+} channels in rat cerebrocortical membranes.

Materials and methods

TISSUE PREPARATION

Female Wistar rats (250–300 g) were stunned and then decapitated. The brain was removed rapidly, the cerebrocortex detached from its internal structures, placed in Tris HCl 50 mmol litre^{-1}, pH 7.4 at 4 °C, and homogenized using a tissue tearor (setting 5,5 × 30-s bursts). The resulting homogenate was centrifuged at 18000 *g* for 10 min and the pellet resuspended in Tris HCl buffer. This procedure was repeated three times. Membranes were frozen in aliquots at −40 °C.

MEASUREMENT OF [^{3}H]PN200-110 BINDING

All binding assays were performed in 1-ml volumes of Tris HCl buffer for 90 min (the optimal incubation time was determined empirically) at 20 °C using cerebrocortical membranes (approximately 200 μg of protein). Saturation analyses to determine the equilibrium dissociation constant (K_d) and the maximal binding capacity (Bmax) were performed using increasing concentrations of [^{3}H]PN200-110 (0.02–2.0 nmol litre^{-1}). In this method, as the concentration of label increases, the binding sites

saturate (analogous to saturation of an enzyme reaction for determination of K_m and Vmax) and the concentration at which specific binding saturates is used to determine Bmax (see fig. 1). It follows that the concentration of ligand that yields half the Bmax is the K_d. Non-specific binding was defined in the presence of excess (10^{-5} mol litre^{-1}) nifedipine. After incubation, each sample was filtered under vacuum through Whatman GF/B filters using a Brandel cell harvester to separate bound and free radioactivity. Filter retained (bound) radioactivity was extracted for at least 8 h in 4 ml of scintillation fluid before estimation using a beta scintillation counter. The estimated radioactivity was quench corrected with an average [^{3}H] counting efficiency of 60.4%. In order to determine if an agent interacted with L-type Ca^{2+} channels, the dihydropyridine binding site was labelled with [^{3}H]PN200-110. Increasing concentrations of unlabelled displacer (anaesthetic agents) were then added. Displacement of [^{3}H]PN200-110 binding by the anaesthetic agents indicates that they are interacting at the same site as the radiolabel, that is the α_1 subunit of the L-type Ca^{2+} channel. A fixed concentration of [^{3}H]PN200-110 (0.2 nmol litre^{-1}) was displaced by the following unlabelled agents: thiopentone ($n = 6$; 10^{-7}–10^{-3} mol litre^{-1}), pentobarbitone ($n = 6$; 10^{-7}–10^{-3} mol litre^{-1}), ketamine ($n = 6$; 10^{-4}–10^{-2} mol litre^{-1}, $n = 4$; 10^{-7}–10^{-3} mol litre^{-1}), etomidate ($n = 6$; 3×10^{-7}–10^{-4} mol litre^{-1}), propofol ($n = 6$; 3×10^{-7}–10^{-4} mol litre^{-1}) and alphaxalone ($n = 6$; 3×10^{-7}–10^{-4} mol litre^{-1}). A non-anaesthetic barbiturate, barbituric acid ($n = 6$; 10^{-7}–10^{-3} mol litre^{-1}) and nifedipine ($n = 5$; 10^{-5}–3×10^{-13} mol litre^{-1}) were examined as negative and positive controls, respectively. Agents were dissolved in Tris HCl buffer as follows; thiopentone (100 mmol litre^{-1} stock in NaOH 0.1 mol litre^{-1}), pentobarbitone and barbituric acid (50 mmol litre^{-1} stock in distilled water), propofol (100 mmol litre^{-1} stock in DMSO), alphaxalone and nifedipine (50 mmol litre^{-1} stock in DMSO), etomidate (50 mmol litre^{-1} stock in HCl 0.1 mol litre^{-1}) and ketamine (500 mmol litre^{-1} stock in distilled water). Appropriate solvent concentrations were added to control tubes. In addition, a full dose–response curve for the effects of DMSO ($n = 6$) was constructed and indicated that 1% DMSO, which is the highest concentration used in these studies, produced only 3±1% displacement. The highest anaesthetic concentration used was limited by agent solubility.

DATA ANALYSIS

Specific binding was calculated as the difference between total and non-specific binding. Bmax and K_d were obtained from Scatchard plots. In displacement studies, the concentrations of displacer producing 25% and 50% displacement of specific binding (IC_{25} and IC_{50}) were obtained by computer-assisted curve fitting (Graphpad-Prism) and corrected for the competing mass of [^{3}H]PN200-110 according to Cheng and Prusoff [13] to yield the affinity constant (K_{25} and K_{50}). All data are expressed as mean (SEM).

Results

Binding of [^{3}H]PN200-110 was time- (fig. 1A) and dose- (fig. 1B) dependent. Bmax and K_d values estimated from Scatchard plots (fig. 1C) were 152 (14) fmol/mg protein and 59 (3) pmol litre^{-1}, re-

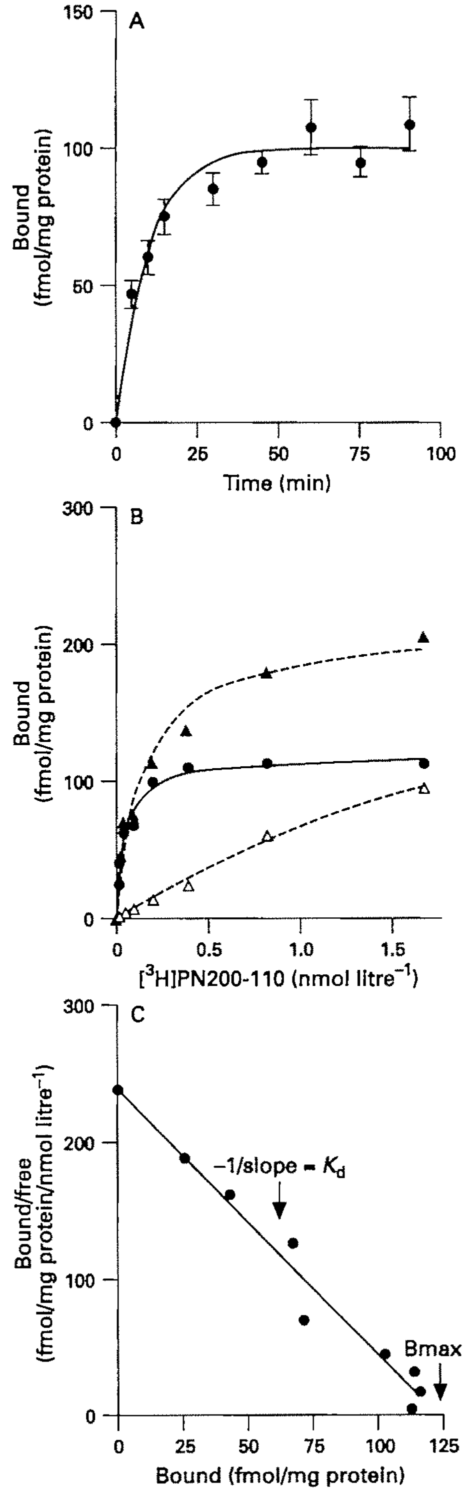

Figure 1 Binding of [^{3}H]PN200-110 to rat cerebrocortical membranes was time- (A) and dose- (B) dependent. In A, [^{3}H]PN200-110 concentration was approximately 0.2 nmol litre^{-1}. C = Scatchard transformation of the specific binding curve in B (● = specific, ▲ = total and △ = non-specific binding) and was used to determine Bmax and K_d. Data are mean, SEM ($n = 5$) in A and from a representative experiment (from $n = 5$) in B and C.

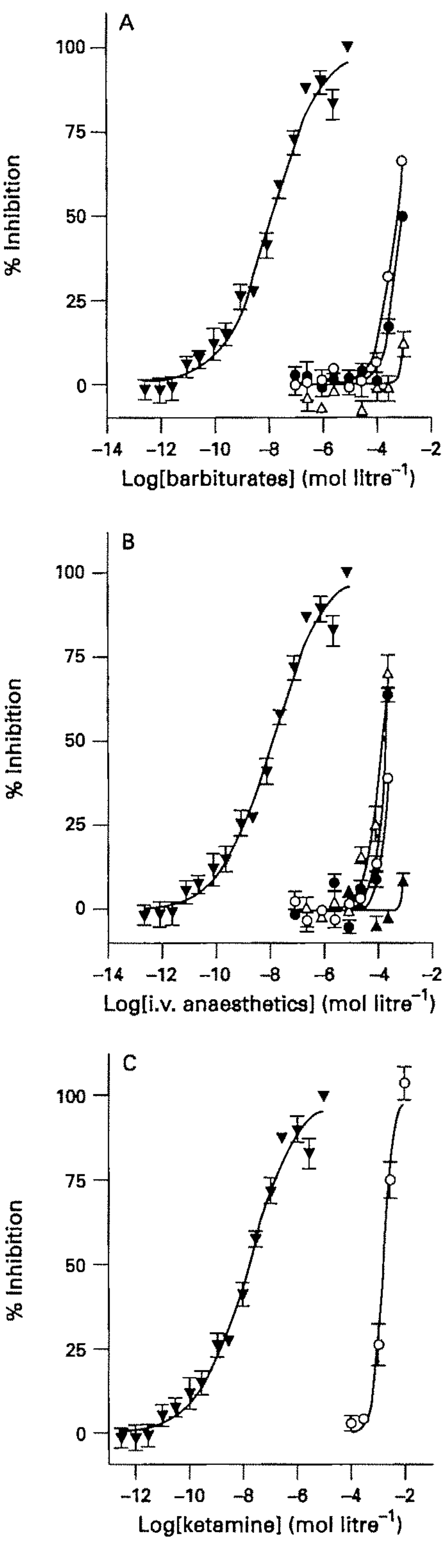

Figure 2 [^{3}H]PN200-110 binding (approximately 0.2 nmol litre^{-1}) was displaced dose-dependently by anaesthetic barbiturates (thiopentone (○), pentobarbitone (●), barbituric acid (△)) (A), propofol (○), etomidate (●), alphaxalone (△) and ketamine (▲) at anaesthetic concentrations (B) and ketamine (○) at local anaesthetic concentrations (C). Nifedipine (▼) is included as a high affinity reference compound. Data are mean, SEM (n = 4–6).

spectively. Nifedipine displaced [^{3}H]PN200-110 binding with a K_{50} of 3.2 (0.6) nmol litre^{-1} (n = 5). All i.v. anaesthetics displaced specific [^{3}H]PN200-110 binding in a dose-dependent manner (fig. 2A–C)

Table 1 Effects of anaesthetics on [^{3}H]PN200-110 binding (mean (SEM))

Agent	n	K_{50} (µmol litre^{-1})	K_{25} (µmol litre^{-1})
Thiopentone	6	134 (6)	48 (2)
Pentobarbitone	6	211 (6)	95 (7)
Propofol	6	97 (5)	40 (2)
Etomidate	6	36 (1)	25 (2)
Alphaxalone	6	34 (5)	17 (3)
Ketamine	6	377 (49)	198 (16)

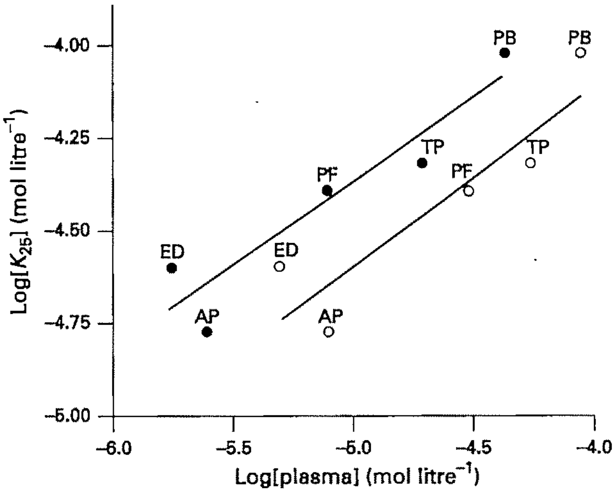

Figure 3 Correlation between binding K_{25}, peak serum concentrations and wakening plasma concentrations of alphaxalone (AP), etomidate (ED), propofol (PF), thiopentone (TP) and pentobarbitone (PB). ● = Awake ($r^2 = 0.0880$, $P = 0.0184$), ○ = peak ($r^2 = 0.824$, $P = 0.0333$).

with K_{25} and K_{50} values shown in table 1. Barbituric acid was ineffective. Ketamine displaced [^{3}H]PN200-110 only at high, local anaesthetic concentrations [14, 15] (fig. 2C). With the exception of ketamine, there was a significant correlation between K_{25} ($r^2 = 0.834$, $P = 0.0333$) (fig. 3) and K_{50} ($r^2 = 0.960$, $P = 0.0035$) and peak plasma concentrations during anaesthesia [16–18]. In addition, there was a significant correlation between plasma concentrations on wakening and both K_{25} ($r^2 = 0.843$, $P = 0.0278$) and K_{50} ($r^2 = 0.965$, $P = 0.0028$) (fig. 3).

Discussion

In this study, our data suggest that i.v. anaesthetic agents interact with the DHP binding site on neuronal L-channels based on the observed correlation between K_{25} and K_{50} and peak plasma concentrations during major surgery or deep sedation [16–18], and plasma concentrations seen on awakening from anaesthesia [17, 19, 20]. Recent reports, however, have suggested that the GABA$_A$ receptor may represent a critical target site for general anaesthesia with voltage-sensitive Ca^{2+} channels being less or unimportant as several anaesthetics produce stereospecific inhibition of Cl$^-$ flux through the GABA$_A$ receptor and the IC$_{50}$ for Ca^{2+} channel inhibition by volatile anaesthetic agents exceeds MAC [19]. One important question for consideration is what degree of inhibition is clinically relevant?

Should a comparison with 50 % inhibition of *in vitro* events be made? It is inconceivable that the central nervous system or cardiovascular system could withstand this degree of inhibition, yet this comparison has been made (e.g. MAC in the whole animal compared with IC_{50} channel activity [19]). Several studies [19, 21, 22] have suggested that clinically relevant concentrations of anaesthetics inhibit neurotransmitter release with only 20–30 % inhibition in Ca^{2+} entry. We have therefore argued that it may be more relevant to compare lower degrees of inhibition, for example 25 % [23]. The data in this article used total peak serum concentrations and those seen on wakening [16–20]. After accounting for varying degrees of protein binding the free drug concentration would be lower. It has been suggested that the relevant anaesthetic concentration for *in vitro* studies is the free (unbound) aqueous concentration at the appropriate end-point for general anaesthesia. However, it should be borne in mind that many i.v. anaesthetic agents [24–27] are concentrated in the brain and their concentration at the target site (the channel) may be similar to the concentration in the brain. As only unbound anaesthetics can pass through the blood–brain barrier, the degree of protein binding is clearly important. However, we should also consider that a new equilibrium which restores the free concentration occurs after a proportion of the free anaesthetic has left the plasma and entered the brain. Therefore, both free and bound (as a pool to replenish the free drug) anaesthetics could be available for diffusion, although the diffusion rate must be dependent on free concentration [28]. In our study, displacement of [^{3}H]PN200-110 binding with i.v. anaesthetics was measured at 90 min (a time at which equilibrium with the brain would have occurred), and therefore we feel that "total" drug concentration may reflect that seen at the target site in the brain. Interestingly, Winters and colleagues [29] examined the influence of albumin on thiopentone action in the rat. In their study they showed that although albumin 400 mg kg^{-1} i.v. 15 min before thiopentone reduced the sleeping time by 30 % ($P < 0.01$), the awake concentration of thiopentone in the brain and total plasma concentration was not affected. If only the free concentration is important, a higher plasma concentration of thiopentone at awakening would be expected in the albumin group. Although their study supports our hypothesis, detailed studies are required to estimate accurately the true "at the target" concentration.

In this study we have compared the K_{50} obtained using rat brain with human serum concentrations during anaesthesia. Although anaesthetic requirements differ between species, there is still close correlation for anaesthetic potencies between species (e.g. a good correlation exists between human MAC and mouse ED_{50} to abolish the righting reflex [30]). Therefore, we suggest that the K_{50} obtained in this study using rat cerebrocortical membranes is likely to be comparable with human serum concentrations.

Several *in vivo* studies [3–5] have suggested that the neuronal L-type Ca^{2+} channel DHP binding site may be involved in the mechanism of general anaesthesia. Dolin and co-workers found that the DHP L-type Ca^{2+} channel blocker, nitrendipine, increased the general anaesthetic potencies of ethanol and pentobarbitone [3], and benzodiazepines [4], while the DHP L-channel activator, Bay K 8644, reduced the anaesthetic action of benzodiazepines [4]. Horvàth, Szikszay and Benedek [5] also reported that Bay K 8644 significantly increased the onset time of hypnosis and decreased the anaesthetic potency of dexmedetomidine, while verapamil (L-channel blocker) significantly augmented the hypnotic–anaesthetic action. However, if L-channels are target sites for anaesthetic agents then why are L-channel blockers not anaesthetic agents in their own right? This may be explained by poor access to the brain for some L-channel blockers [31]. Interestingly, in a long-term, multicentre study, flunarizine, a non-selective Ca^{2+} channel antagonist which does pass the blood–brain barrier, was reported to produce somnolence as a side effect in 42 % of migraine patients [32]. In addition, L-channel blockers have been reported to exert an antinociceptive action, which is an important component of general anaesthesia, for both rats and humans [33–36]. Electrophysiological studies also showed that pentobarbitone [9] and propofol [10] inhibited neuronal L-type Ca^{2+} channels. Moreover, volatile anaesthetics have been reported to inhibit the DHP binding site in rat brain membranes [11, 12] consistent with our hypothesis. Collectively we feel that these data suggest that the DHP binding site on the L-type voltage sensitive Ca^{2+} channel may be a target site for general anaesthetic agents.

Ketamine could only inhibit DHP binding at concentrations in excess of those required to produce general anaesthesia. However, ketamine has local anaesthetic properties because it can produce not only general anaesthesia but also local anaesthesia (such as i.v. regional anaesthesia) [14, 37]. Durrani and colleagues [14] reported that > 0.3 % ketamine (approximately 10^{-2} mol $litre^{-1}$) produced adequate regional anaesthesia with complete sympathetic, sensory and motor block. These concentrations are in agreement with our studies and suggest that the local anaesthetic action of ketamine may include Ca^{2+} channel block. Clearly a wide range of local anaesthetic agents will need to be examined to confirm or refute this hypothesis, although recent studies suggest that Ca^{2+} channels may be involved in the mechanism of action of local anaesthetics [38, 39]. It should also be noted that ketamine is an exception to the "GABA" hypothesis in that this agent does not interact with $GABA_A$ receptors [19]. As ketamine is a non-competitive NMDA channel blocker [40] it is possible that this agent could similarly block the aqueous pore of the L-channel. Indeed, channel block by ketamine is supported by the observed inhibition of K^+-evoked noradrenaline release from SH-SY5Y human neuroblastoma cells [41] with simultaneous inhibition of K^+-evoked Ca^{2+} entry. Does inhibition of DHP binding correlate with inhibition of Ca^{2+} influx? Certainly, Toll [42] showed, using PC12 cells, that the IC_{50} of nifedipine (2.7 (0.3) nmol $litre^{-1}$) for $^{45}Ca^{2+}$ uptake was similar to that (1.6 (0.4) nmol $litre^{-1}$) of [^{3}H]nitrendipine binding. Other investigators have also suggested that nifedipine reduces Ca^{2+} influx, with IC_{50} values using neuronal cells such as NCB-20 cells [43], NG08-15 cells [44] and PC12 cells [21] similar to the K_{50} reported here. However, while we suspect that DHP displacement with anaesthetic agents may produce a similar reduction in Ca^{2+} influx we have no data in this tissue to support this notion. However, in SH-SY5Y human neuroblastoma cells we have shown [45] that thiopentone and propofol inhibited K^+-evoked increases in intracellular Ca^{2+} with IC_{50} values of 121 and 124 µmol litre^{-1}, respectively, in good agreement with the K_{50} values also reported here.

In conclusion, we suggest that the DHP binding site of L-type voltage sensitive Ca^{2+} channels may be a target site for i.v. anaesthetic agents.

Is inhibition of dopamine uptake relevant to the hypnotic action of i.v. anaesthetics?

H. KEITA, J. B. LECHARNY, D. HENZEL, J. M. DESMONTS AND J. MANTZ

Summary

We have examined the effects of ketamine, etomidate, propofol and thiopentone on the uptake of [^{3}H]-dopamine into rat striatal synaptosomes. [^{3}H]-dopamine uptake (5 min, 37 °C) was potently inhibited by nomifensine, a classical inhibitor of the dopamine carrier. All anaesthetics induced concentration-related inhibition of the uptake process, values for IC_{50} being 4.6×10^{-6}, 5.5×10^{-5}, 1.5×10^{-4} and 2.7×10^{-4} mol litre^{-1} for ketamine, etomidate, propofol and thiopentone, respectively. For all anaesthetics, inhibition of [^{3}H]-dopamine uptake was reversible with a non-competitive profile. These data suggest that inhibition of striatal dopamine uptake may represent a relevant target site for some, but not all, i.v. anaesthetics. (*Br. J. Anaesth.* 1996; **77**: 254–256)

Key words

Anaesthetics i.v., ketamine. Anaesthetics i.v., thiopentone. Anaesthetics i.v., etomidate. Anaesthetics i.v., propofol. Nerve, neurotransmitters.

There is a large body of evidence to suggest that enhancement of inhibitory (primarily $GABA_A$-mediated) or depression of excitatory (glutamate-mediated) neurotransmission, or both, may account for the dominant depressant effects of anaesthetics in the central nervous system. However, some experimental data suggest that other neuronal subpopulations, such as the striatal dopamine neurones, may contribute to some anaesthetic mechanisms. Indeed, an inverse correlation has been established between halothane anaesthetic requirements and the striatal dopamine content in mice [1]. Furthermore, striatal extracellular levels of dopamine or its metabolites were increased significantly during halothane anaesthesia in rats, which might be explained in part by block by volatile anaesthetics of the dopamine transporter [2].

The recent cloning of the DNA dopamine transporter gene in mammals has allowed extensive characterization of the pharmacology of this protein. Because of the hydrophobicity of the dopamine carrier, dopamine uptake may represent a target not only for volatile, but also for structurally heterogeneous i.v. anaesthetics. In support of this, ketamine and structurally related compounds have been shown to potently block dopamine uptake in the central nervous system [3]. Whether other i.v. anaesthetics can modulate the activity of the dopamine carrier remains to be determined. Therefore, the aim of this study was to examine the effects of i.v. anaesthetics on the uptake of dopamine into isolated, purified striatal nerve terminals (synaptosomes).

Materials and methods

Handling procedures, as written in the Guide for the Care and Use of Laboratory Animals, were followed throughout. Experiments were performed on male Sprague Dawley rats (Iffa-Credo, France) weighing 200–225 g and housed on a 12:12 light–dark cycle with food and water *ad libitum*. Animals were killed by stunning and decapitation, and striata removed rapidly from the brains and placed into ice cold sucrose 0.32 mol litre^{-1} containing EDTA 1 mmol litre^{-1}, dithiothreitol 0.25 mmol litre^{-1} and adjusted to pH 7.4. Synaptosomes were isolated and purified on a four-step Percoll gradient and diluted to protein 0.16 mg ml^{-1} with artificial cerebrospinal fluid (CSF) at 4 °C (mmol litre^{-1}): NaCl 126.5; $NaHCO_3$ 27.5; KCl 2.4; KH_2PO_4 0.5; $CaCl_2$ 1.1; $MgCl_2$ 0.83; Na_2SO_4 0.5; glucose 5.9; pargyline 10^{-2}; ascorbic acid 1; the pH was adjusted to 7.3 with a 95:5 v/v oxygen–carbon dioxide mixture.

Uptake was initiated by adding [2, 5, 6 ^{3}H]-dopamine (Amersham, England, 44 nmol litre^{-1}, 24 Ci mmol^{-1}, 1 mCi ml^{-1}) to the synaptosomal suspension at 37 °C. This was performed in either the absence of any pharmacological or anaesthetic agent (control), or both, or the presence of various concentrations of nomifensine 10^{-8}–5×10^{-5} mol litre^{-1} (Research Biochemical Incorporated, France) or ketamine (Sigma, USA) 10^{-6}–10^{-3} mol litre^{-1}, etomidate 10^{-6}–5×10^{-4} mol litre^{-1}, propofol 10^{-6}–5×10^{-4} mol litre^{-1} or thiopentone (Specia, France) 10^{-6}–10^{-3} mol litre^{-1}. Etomidate and propofol were dissolved in dimethylsulphoxide (Merck, Germany). After 5-min incubation, the mixture was vacuum filtered through glass filters (Whatman, GF/F, 0.70-µm retention capacity) and washed with 10 ml of ice-cold CSF. The radioactivity retained on the filters was extracted with NaOH 0.1 mol litre^{-1} and measured by liquid

Correspondence to J.M.

scintillation in Aquasol 2 (New England Nuclear, USA). Specific [^{3}H]-dopamine uptake was considered the difference between the radioactivity measured in both the presence and absence of nomifensine 10^{-5} mol litre^{-1}.

To determine if the effects of anaesthetics were not caused by irreversible synaptosomal damage, [^{3}H]-dopamine uptake was examined after removal of the anaesthetic from the buffer–synaptosomal suspension by vacuum and stirring rapidly for 30 min. Aliquots were removed at 15 and 30 min from an uptake mixture initially containing a concentration of anaesthetic corresponding to that inhibiting 50 % of specific high affinity [^{3}H]-dopamine uptake (IC_{50}), and [^{3}H]-dopamine uptake was determined as a function of the time that the mixture had been exposed to vacuum and stirring. Control experiments were also performed in parallel to allow comparison with anaesthetic-free mixtures exposed to the same conditions of vacuum and stirring.

To distinguish between competitive and non-competitive mechanisms of any observed inhibition of [^{3}H]-dopamine uptake by anaesthetics, the kinetics of anaesthetic-induced inhibition were investigated by incubating synaptosomes (37 °C, 5 min) with increasing concentrations [^{3}H]-dopamine (44–530 nmol litre^{-1}). The reaction was stopped by addition of ice-cold CSF followed by vacuum filtration, and the radioactivity retained on the filters was measured. The kinetic variables of the reaction (Vmax, K_m) were determined in the absence (control) and presence of a fixed concentration of anaesthetic corresponding to the IC_{50} value.

Concentration–response curves were generated by computer and IC_{50} values for inhibition of [^{3}H]-dopamine were calculated using the GraphPAD Software (San Diego, CA, USA). Results were considered reliable only if they had been reproduced in at least four independent experiments (each run in triplicate). Kinetic variables were analysed by ANOVA followed by the Student's t test corrected for the number of comparisons. $P < 0.05$ was considered the threshold for significance.

Results

Synaptosomal [^{3}H]-dopamine uptake increased with time and concentration and the mean value was 1.98 (SD 0.08) pmol litre/mg protein after 5 min incubation. It was potently blocked by nomifensine, a classical inhibitor of catecholamine uptake ($IC_{50} = 2.4 \times 10^{-7}$ mol litre^{-1}) (fig. 1). Non-specific uptake was always less than 5 % of the total radioactivity retained on the filters. The effects of ketamine, etomidate, propofol and thiopentone on [^{3}H]-dopamine uptake are displayed in figure 1.

For each anaesthetic tested, there was a concentration-related inhibition of the uptake of [^{3}H]-dopamine. Values for IC_{50} were 4.6×10^{-6}, 5.5×10^{-5}, 1.5×10^{-4} and 2.7×10^{-4} mol litre^{-1} for ketamine, etomidate, propofol and thiopentone, respectively. The 95 % confidence intervals were 7.6×10^{-7}–2.8×10^{-5} mol litre^{-1} for ketamine, 2×10^{-5}–10^{-4} mol litre^{-1} for etomidate, 5.6×10^{-5}–4×10^{-4} mol litre^{-1} for propofol and 2.3×10^{-5}–3.4×10^{-3} mol litre^{-1} for thiopentone. Dimethylsulphoxide did not affect [^{3}H]-dopamine uptake by itself.

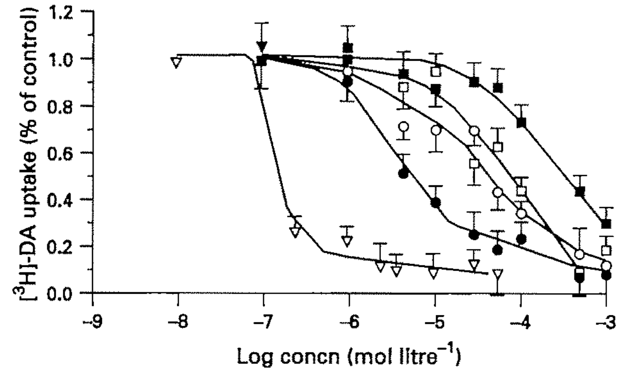

Figure 1 Inhibition of [^{3}H]-dopamine (DA) uptake by increasing concentrations of nomifensine (▽), ketamine (●), etomidate (○), propofol (□) and thiopentone (■). Data are mean, SD, and were obtained from at least four independent experiments.

Inhibition of the uptake process was totally reversible for each of the anaesthetics. Indeed, uptake of [^{3}H]-dopamine measured 15 and 30 min after removal of the anaesthetic from the solution was not significantly different from that observed in a time-dependent control. Dopamine uptake at 15 and 30 min after wash-out was mean 89 (SD 7) % and 94 (6) %, 84 (11) % and 96 (8) %, 87 (10) %, and 92 (9) %, 85 (9) % and 97 (6) % of control values for ketamine, etomidate, propofol and thiopentone, respectively.

All compounds exhibited a non-competitive profile, as assessed by both the lack of significant difference in K_m and the significant decrease in Vmax values observed between control experiments and those containing anaesthetics: Vmax (pmol/mg protein for 3 min) = 27 (6.1) for control, and 11 (2.8) ($P < 0.01$), 14 (3.4) ($P < 0.01$), 19 (4.1), ($P < 0.05$) and 21 (5.0) ($P < 0.05$) for ketamine, etomidate, propofol and thiopentone, respectively; K_m (nmol litre^{-1}) = 99 (18) for control, and 97 (19) (ns), 94 (18) (ns), 98 (16) (ns) and 101 (19) (ns) for ketamine, etomidate, propofol and thiopentone, respectively.

Discussion

We have shown that ketamine, etomidate, propofol and thiopentone inhibited the uptake of [^{3}H]dopamine in a reversible and non-competitive manner. The concentrations of ketamine and etomidate reported here are in agreement with those found in the plasma of anaesthetized humans, while those of propofol and thiopentone were likely to be outside the clinical range, even though such blood concentrations have been observed with propofol shortly after induction of anaesthesia [4]. Also, reversibility of effects is consistent with a clinically relevant action of i.v. anaesthetics on the dopamine carrier.

The anaesthetics exhibited a non-competitive profile of inhibition of [^{3}H]-dopamine uptake. Inhibition of dopamine uptake by isoflurane is non-competitive also and it exhibits no stereoselectivity [2]. Interestingly, not all transporters are relevant target sites for anaesthetic agents, as the striatal GABA carrier is also inhibited by some i.v. agents used at clinically relevant concentrations, while the glutamate transporter is not [5, 6]. For example, propofol exhibits more potent inhibitory effects on the GABA than on the dopamine carrier, whereas the opposite is true for ketamine [5] or other structurally related compounds such as phencyclidine [3]. Although the molecular mechanisms (direct effect on the carrier or actions via the lipid environment) whereby these anaesthetics block dopamine uptake remain to be elucidated, these results suggest that the anaesthetic carrier interactions exhibit some degree of specificity.

By increasing dopamine in the synaptic cleft, block of dopamine uptake may favour inhibitory neurotransmission, as stimulation of the striatal dopamine D2 postsynaptic receptors results in hyperpolarization. These results suggest that dopamine uptake might represent a target for some, but not all, i.v. anaesthetics.

Myocardial extraction of bupivacaine in anaesthetized sheep and by hearts of sheep and rats *in vitro*

H. FOTH, T. SCHRÖDER, B. KRAUS, J. P. HERING, F. B. M. ENSINK AND G. HELLIGE

Summary

We observed the *in vivo* kinetics of bupivacaine in the cardiopulmonary system, particularly in the pulmonary artery, the upper part of the descending aorta and the coronary sinus of anaesthetized sheep, each of which received a high dose infusion into the central vein. In some experiments dilution curves were monitored for the non-extracted dye, indocyanine green. Concentrations of bupivacaine were approximately 20% lower in the aorta than in the pulmonary artery. This gradient of bupivacaine was present across the lung for 5–10 min. Concentrations of bupivacaine in the coronary venous plasma were also markedly lower than at the arterial site. Initially more than 50% of the amount of bupivacaine at the arterial site was removed by the heart. Later, the myocardial extraction ratio decreased and plateaued at a value of 0.30–0.40. At this time, concentrations of bupivacaine in the pulmonary artery were approximately 12 μg ml^{-1}. Therefore, approximately 0.3–0.6 mg of bupivacaine were extracted per minute by the sheep heart *in vivo*. On the other hand, isolated perfused rat hearts did not substantially remove bupivacaine (2 μg ml^{-1}) from the medium. Approximately one-third of ^{14}C-bupivacaine was retained in slices of rat and sheep myocardial tissue. However, there was no evidence that metabolism played a substantial role in the cardiac kinetics of bupivacaine. (*Br. J. Anaesth.* 1996; **77**: 257–264)

Key words

Anaesthetics local, bupivacaine. Liver, metabolism. Pharmacokinetics, bupivacaine. Rat. Sheep. Model, rat. Heart, isolated preparation. Lung.

Amide-linked local anaesthetic drugs, such as bupivacaine, mepivacaine or prilocaine, are used widely for regional anaesthesia. Usually these drugs are injected extradurally at relatively high doses. Almost the whole amount of drug enters the circulation because the rate of degradation at the site of injection is negligible [1, 2]. Accordingly, these drugs reach relatively high concentrations in plasma which are close to those at which toxic effects are likely to occur [3, 4].

Adverse effects in the central nervous system, such as convulsions, may occur at concentrations which are 2–4-fold higher than those which are observed in the course of regional anaesthesia. On the other hand, cardiovascular functions are affected at higher concentrations than those which cause side effects in the central nervous system. The ratio between clinically effective doses and those producing non-fatal toxicity are not substantially different between commonly used local anaesthetics. However, cardiotoxic events with a fatal outcome appear to be associated with bupivacaine in particular [5, 6]. This feature of bupivacaine may be explained partly by pharmacokinetic properties such as disposition in the myocardial tissue.

In this study we monitored concentrations of bupivacaine *in vivo* in the cardiopulmonary system, that is in the pulmonary artery, upper part of the descending aorta and coronary sinus. Bupivacaine was infused into the central vein at a relatively high infusion rate. *In vitro* experiments using perfused rat hearts or sliced myocardial tissue of rats and sheep were performed in order to determine if metabolism is important for the cardiopulmonary kinetics of bupivacaine.

Materials and methods

EXPERIMENTS ON SHEEP *IN VIVO*

The experiments were approved by the appropriate governmental committee according to the Animal Protection Law. Adult sheep (body weight 45–97 kg) were anaesthetized with a continuous infusion of midazolam 0.25 mg kg^{-1} min^{-1} and buprenorphine 0.01 mg kg^{-1} min^{-1}. The trachea was intubated and the lungs ventilated artificially with 70% nitrous oxide in oxygen. A 7-French gauge cannula was inserted into the right atrium via the right jugular vein and into the upper part of the descending aorta via the femoral artery. The correct position of all catheters was verified by x-ray. A Morawitz cannula was inserted into the right jugular vein and positioned in the ostium of the coronary sinus where it was blocked to avoid mixed sampling of central venous and coronary venous blood. The tip of this cannula was directed 1 cm into the coronary sinus. The hemiazygos vein, which in sheep drains into the coronary sinus, was blocked by a Fogarty catheter. Blood from the coronary sinus (60–80 ml min^{-1}/100 g left ventricle) was directed into an external

electromagnetic flow probe (501 D, Carolina Medical Electronics, Inc. King, NC, USA) and directed back from the extracorporeal catheter into the left jugular vein via a shunt (for further details see [7]). A thermodilution Swan-Ganz catheter (F7, Arrow Int. Reading, PA, USA) was inserted. Pulmonary arterial blood was obtained from a sampling port of this catheter. Cardiac output was measured by the thermodilution technique (BN 6560, August Fischer KG, Goettingen, Germany). At least two measurements were made and the mean value recorded. Additionally, other variables such as arterial pressure and electrocardiogram, plasma electrolyte, oxygen and lactate concentrations were recorded.

The experiments were scheduled originally for studies on the intravascular distribution and pharmacodynamic properties of investigational drugs (see table 1), such as spontaneously degrading ultrasonic bubbles (experiments 108, 120) or inhibitors of phosphodiesterases (experiments 141, 169, 171, 172). The ultrasonic bubbles SHU 508 are very short-lived because of their physicochemical instability and the inhibitor of phosphodiesterase, R80122, exhibits its pharmacodynamic action only for a short period of time. Flow measurements (Doppler sonography) were performed in experiment 192 after intra-coronary administration of organic nitrate and papaverine. Other experiments were performed to obtain reference values in controls (118) and in animals after transient mild hyperthermia of the hind limb (experiment 149), or after transient lactate acidosis (experiment 168). Therefore, these animals received no investigational drugs before bupivacaine. When haemodynamic and other major clinical variables returned to stable baseline values, racemic bupivacaine, was infused into a catheter introduced into the central vein at a rate of 0.2 mg kg^{-1} min^{-1}. The tip of this tubing was positioned near the right atrium. In two experiments another infusion regimen was used: one sheep (experiment 108) received 0.05, 0.1, 0.2 and 0.4 mg kg^{-1} min^{-1} each for 10 min. Another animal was dosed with 0.1 mg kg^{-1} min^{-1} for 0–30 min and 0.2 mg kg^{-1} min^{-1} for 30–45 min (experiment 118). In experiment 108, death occurred when the highest dose was administered. The other experiments were terminated by injection of potassium chloride.

In some experiments (149, 168, 169 and 186) indocyanine green (ICG) 0.05 mg kg^{-1} min^{-1} (approximately 80 mg Cardiogreen, Paesel, Frankfurt, FRG) was infused concomitantly with bupivacaine into the central vein just before the right atrium. Blood samples (5 ml) were obtained from the pulmonary artery, descending aorta and coronary sinus 1, 2, 5, 7, 10, 15, 20, 25 and 30 min after the start of infusion. Between the site of infusion and the first site of blood sampling, blood passed through the right atrium and ventricle. The plasma fraction was stored at −20 °C until analysis by HPLC.

IN VITRO EXPERIMENTS

Isolated rat hearts were obtained from male Wistar rats during urethane anaesthesia. The organs were prepared according to the Langendorff technique and were connected to the perfusion apparatus (Langendorff apparatus modified according to Schuler, Hugo Sachs Elektronik KG, March, Germany). The experiments were performed without an external pacemaker. The isolated rat hearts were perfused with oxygenated Krebs–Ringer–bicarbonate buffer supplemented with D-glucose 2 mg ml^{-1} at a constant pressure of 52.5 mm Hg. Sham perfusions were performed under identical conditions but without insertion of a rat heart.

Sheep myocardial tissue was obtained from a local slaughterhouse. When the trachea-lung-heart system was removed from the animal, a 5–10-g specimen of the ventricle was obtained immediately and transferred into ice-cold saline solution containing heparin 20 I.E. ml^{-1}. Incubations of tissue slices were started approximately 1 h after the animal had been killed. Rat hearts were obtained from untreated male Wistar rats after neck dislocation and bleeding via an incision of the jugular vein. Slices of rat and sheep hearts of 0.5 mm thickness (0.2 g wet tissue/ml) were incubated in Krebs–Ringer–bicarbonate buffer or phosphate buffer (66 mmol litre^{-1} pH 7.4) supplemented with bovine serum albumin 15 mg or D-glucose 1 mg ml^{-1}. The tissue–buffer solutions (5–6 ml) were incubated with ^{14}C-bupivacaine (gift from Astra, Södertalje, Sweden) 0.3 (rat) or 2 (sheep) µg ml^{-1} in 25-ml Erlenmeyer vials under a continuous stream of carbogen. Ten samples, each 200 µl, were taken from the medium and stored at −20 °C until analysis by thin layer chromatography (TLC).

ANALYSIS

ICG kinetics were recorded spectrophotometrically in plasma samples using an Eppendorf photometer 2116 at a wavelength of 623 nm. Unlabelled bupivacaine was quantified by non-enantioselective HPLC, as described previously [8]. Briefly, the samples were spiked with internal standards (mepivacaine or pentacaine) and extracted with n-hexane under alkaline conditions. The organic extract was re-extracted into 100 µl of 50 % H_3PO_4 0.2 mol litre^{-1}–50 % n-hexane. A fraction of the acid layer (20 or 50 µl) was injected onto a 5-µm NC phenyl-hypersil analytical column (Bischoff, Nettetal, FRG). HPLC was run at 1 ml min^{-1} using a mobile phase of 60 % acetronitrile–40 % H_3PO_4 0.01 mol litre^{-1}, pH 3.3. UV absorbance was monitored at 214 nm. The analytical limit of detection was approximately 10 ng ml^{-1} for a 200-µl sample. The variation of results for repeated analysis of low concentrations was 1.5–4.8 % (inter-day) and 1.1–3.7 % (intra-day).

^{14}C-labelled bupivacaine was extracted from the samples, as described above, with the exception that either n-hexane or dichloromethane was used. Bupivacaine and ^{14}C-labelled products were separated on silica gel-coated plastic sheets by TLC in chloroform–methanol–triethylamine 20:1:0.1 (v/v/v). The lanes were scanned by a TLC linear analyser LB 2842 (Berthold, Wildbad, FRG). Also, HPLC was applied to see if metabolites had been formed.

CALCULATIONS AND STATISTICS

Pulmonary and cardiac extraction ratios were calculated from the concentration in the inflow, C_{in}, that is pulmonary–arterial or arterial plasma, and the outflow, C_{out}, that is arterial or coronary venous plasma, by

$$(C_{in} - C_{out})/C_{in}$$

The pharmacokinetic variables of bupivacaine elimination by isolated rat hearts, such as elimination half life ($T_{\frac{1}{2}}$) and steady state volume of distribution (V^{ss}) were calculated from the concentration *vs* time curve using a standard two-compartmental model assuming first-order elimination kinetics, as described previously [9]. The elimination rate constant (k_{el}) was determined by linear regression analysis from the semi-logarithmic concentration *vs* time curve and volume of distribution was calculated from dose/C_{β}, the intercept of the second part of the semi-logarithmic concentration *vs* time curve extrapolated to time 0.

Results are given as arithmetic mean (SEM) or geometric mean (SEM), where indicated. Statistical analysis was performed either by a two-sided unpaired *t* test or by a paired *t* test (comparison of C_{in} and C_{out}).

Results

EXPERIMENTS *IN VIVO*

Adult sheep ($n = 10$) were scheduled originally for experiments on pharmacokinetic and pharmacodynamic properties of investigational drugs, such as enhancers of the ultrasonic signal and phosphodiesterase inhibitors, or some experiments served as controls; when all variables had returned to baseline values a relatively high dose of bupivacaine 0.2 mg kg^{-1} min^{-1} was infused into the central vein just before the right atrium for 30 min. Two sheep were studied at other infusion rates (see materials and methods).

The time courses of plasma concentrations of bupivacaine in the pulmonary artery, upper part of the descending aorta and coronary sinus are shown in figure 1. At the end of infusion, plasma concentrations were approximately 11 µg ml^{-1} in the pulmonary artery and in the descending aorta (see tables 3, 4). Although these concentrations are relatively high, impairment of cardiac functions was not

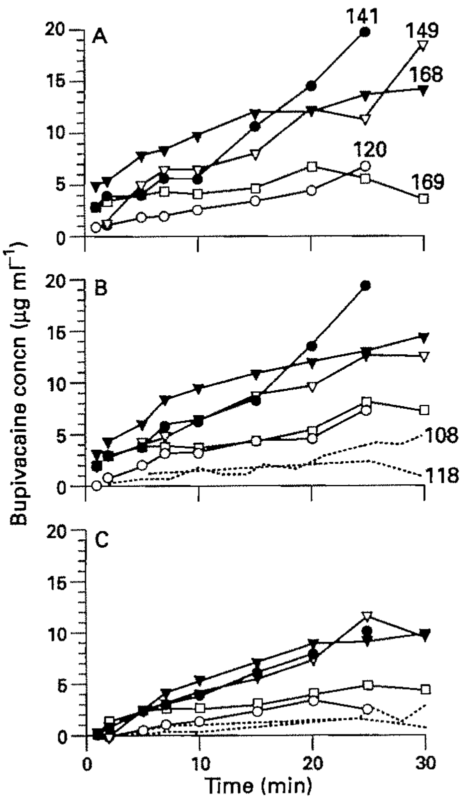

Figure 1 Concentrations of bupivacaine in the plasma of the pulmonary artery (A), upper part of the descending aorta (B) and coronary sinus (C) in anaesthetized female sheep. Bupivacaine was infused into the central vein at a rate of 0.2 mg kg^{-1} min^{-1} over 30 min. The curves depict results from individual experiments. The curves without symbols refer to two pilot experiments where bupivacaine was administered using different rates of infusion.

induced except in experiment 108 (dose-finding experiment) where fatal cardiac failure was intended. Cardiac arrest occurred 5 min after setting the infusion rate to 0.4 $\text{mg kg}^{-1}\ \text{min}^{-1}$. In other cases, vascular resistance of coronary vessels was increased, which indicates that bupivacaine may affect myocardial perfusion under certain circumstances. All other variables, such as arterial pressure, heart rate, stroke volume and vascular resistance, were not markedly impaired (see table 2).

Shortly after the start of infusion the concentration of bupivacaine in plasma samples from the descending aorta was lower than the corresponding value in the pulmonary artery. Thus there was a gradient of bupivacaine concentration across the lung which lasted 5–10 min. In contrast, concentrations of indocyanine green were almost identical in these samples which indicates that only bupivacaine was retained by the lung. The fraction of pulmonary extracted bupivacaine was calculated from concentrations in paired samples from the aorta and pulmonary artery. The results are shown in the lower panel of figure 2 and table 3. Approximately 10 min after starting the infusion, bupivacaine concentrations were almost identical in blood samples obtained before and after the lung, thereby indicating that bupivacaine was extracted by the lung only for a short time.

In our study we have obtained evidence that myocardial tissue may also be an important compartment for the distribution of bupivacaine. Samples from the coronary venous outflow contained

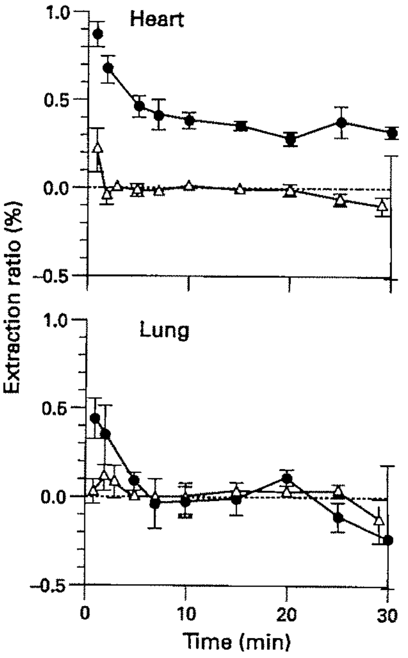

Figure 2 Extraction of bupivacaine by the heart and lung of anaesthetized sheep. Myocardial and pulmonary extraction ratios $((C_{\text{in}} - C_{\text{out}})/C_{\text{in}})$ of bupivacaine (●) and indocyanine green (ICG) (○) in female sheep are given as arithmetic mean, SEM ($n = 5$). ICG was infused concomitantly to bupivacaine in three experiments (149, 168, 169) and in one additional experiment (186) without administration of local anaesthetic.

Table 3 Concentration gradient of local anaesthetics across the lung and heart in adult sheep *in vivo*. Results of individual experiments are shown; rate of infusion 0.2 mg kg^{-1} min^{-1} for 30 min with the exception of *108, 118 (see table 2 and Materials and methods for details). B = bupivacaine, L = lignocaine, P = prilocaine. [a]Concentration below limit of detection; [b]No sample available; [c]Sample obtained at 40 min.

much less bupivacaine than corresponding samples from the arterial site of circulation (fig. 1, tables 3, 4). Immediately after the start of infusion the arteriovenous difference of bupivacaine concentration across the heart reached almost 80 % of the level at the arterial site (fig. 2). Afterwards the gradient of bupivacaine concentration decreased and finally plateaued at approximately 30–40 %. On the other hand, indocyanine green was present in these samples in almost identical concentrations. Thus it must be assumed that bupivacaine was subjected to substantial first-pass extraction by sheep hearts *in vivo*. Other experiments with indocyanine green but without bupivacaine confirmed that the kinetics of indocyanine green which were monitored on-line with a fibreoptic system, were not different at our sampling sites (results not shown).

Similar results concerning myocardial extraction of drugs were obtained in experiments 171, 172 and 192 where other local anaesthetics, lignocaine and prilocaine, were used (see table 3). The extraction ratios of lignocaine and prilocaine appeared to be lower compared with bupivacaine. However, further studies are needed to assess if the rate of myocardial extraction is different for these local anaesthetic drugs.

It is unlikely that the experiments performed before infusion of these drugs substantially affected

Table 5 Kinetics of bupivacaine in isolated perfused rat heart. Values are arithmetic mean (SEM). The perfusion experiments were carried out in a Langendorff perfusion apparatus using bupivacaine 2 μg ml^{-1}. $C_p$max = Highest observed plasma concentration after reaching equilibrium; $C_p$end = concentration at end of experiments. $T_{\frac{1}{2}}$ = elimination half-life; V^{ss} = volume of initial distribution, calculated from the dose and the intercept of the second part of the semi-logarithmic concentration *vs* time curve extrapolated to time 0

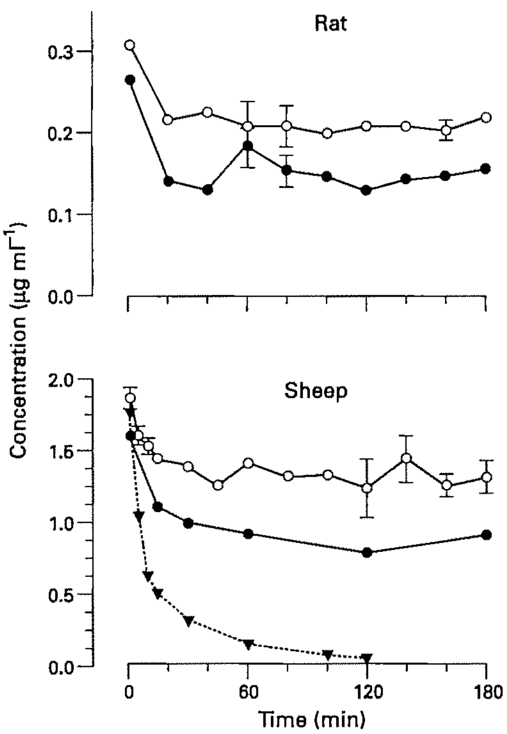

Figure 3 Time course of bupivacaine (●) and total radioactivity (○) in the medium of incubated slices of myocardial tissue. Slices of rat ($n = 5$) and sheep ($n = 4$) hearts were incubated *in vitro* (0.2 g organ/ml) with ^{14}C-labelled bupivacaine 0.3 or 2 μg ml^{-1}. The results of a single experiment with sheep liver slices are included (▼ = bupivacaine).

the pharmacokinetic fate of bupivacaine, lignocaine or prilocaine. All experiments showed almost the same effect, although the animals underwent a very different programme and some served as controls.

EXPERIMENTS *IN VITRO*

In order to evaluate if substantial cardiac extraction of bupivacaine can also be confirmed *in vitro* using organs from small laboratory animals, we studied the kinetics of bupivacaine in the Langendorff preparation of isolated rat hearts. Bupivacaine was administered to the isolated organs in an initial concentration of 2 μg ml^{-1} which corresponds to a dose of approximately 100 μg/g of organ. The time course of bupivacaine concentrations in the medium of isolated perfused rat hearts was almost identical to the reference curve of sham perfusions (table 5). The latter experiments were carried out using the same Langendorff perfusion apparatus but without the isolated organ in order to examine the influence of spontaneous hydrolysis and absorption by the tubing material.

Slices of rat or sheep hearts were incubated with ^{14}C-labelled bupivacaine 0.3 (rat) or 2 (sheep) μg ml^{-1} *in vitro*. Under these circumstances the total load was approximately 1.5 or 10 μg of drug/g of organ. The concentration of bupivacaine in the medium decreased substantially during the first 30 min of incubation which indicates that this compound was bound to tissue proteins (see fig. 3). This tissue-bound fraction accounted for approximately 30–50 % of the total amount of bupivacaine. However, we did not obtain convincing evidence that slices of myocardial tissue of rats or sheep metabolized bupivacaine *in vitro*. In contrast with sheep hearts, slices of sheep liver metabolized ^{14}C-bupivacaine very effectively *in vitro* (see fig. 3, results of a single experiment are shown).

Discussion

Under normal clinical conditions, maximum plasma concentrations of amide-linked local anaesthetics are relatively close to the margin of safety with respect to toxicity [1, 3, 5, 10–12]. Although it is generally believed that the therapeutic index is not substantially different between lignocaine, mepivacaine, prilocaine and bupivacaine, it has been suggested that bupivacaine in particular may be associated with serious cardiac toxicity [5, 6]. In particular, appropriate observations were reported when highly concentrated solutions of bupivacaine had been used. If it is true that the side effects of bupivacaine carry a higher cardiotoxic risk compared with other compounds, this effect may be partly explained by the pharmacokinetic features of this compound, that is a high degree of protein binding and persistence within the tissue because of its long elimination half-life. Our experiments were undertaken in order to evaluate the disposition of bupivacaine in the cardiopulmonary system of sheep *in vivo*.

We achieved relatively high systemic concentrations of bupivacaine in anaesthetized sheep undergoing artificial ventilation. These concentrations exceeded the values of acutely toxic concentrations reported from other studies [6]. However, cardiac functions (stroke volume, arterial pressure, ECG) were not seriously impaired in most of our experiments.

For a short period of time we measured an "arteriovenous" gradient of bupivacaine concentration across the lung. The difference in concentration was highest immediately after the start of infusion and was decreased to almost 0 within 15 min. Thus it may be assumed that initially considerable amounts of bupivacaine were removed from the blood during its passage through the lung. However, this filtering effect of the lung was only short-lived. Similar observations were made for bupivacaine and prilocaine in isolated perfused lungs of rabbits and rats [13–15]. This feature of sheep lung concerning the kinetics of bupivacaine is similar to our findings in a clinical study in patients undergoing extradural anaesthesia [16]. It is likely that pulmonary first-pass extraction of bupivacaine is caused mainly by binding to tissue proteins and that this process is limited by the capacity of binding. It must be assumed that the rate of metabolic elimination of local anaesthetics by the lung is very small. Accordingly, most of the extracted drug is released by the lung into the blood stream and is finally degraded by metabolism at extrapulmonary sites.

The gradient of bupivacaine concentrations between arterial and coronary venous plasma indicates that the sheep heart may have a substantial influence on the pharmacokinetic effect of bupivacaine. This cardiac filter effect was relatively high immediately after the start of infusion. Within the following 10 min the difference in bupivacaine concentration across the heart decreased to approximately 50% of initial values. This might be caused by capacity-limited binding to the tissue. However, afterwards the cardiac extraction ratio of bupivacaine plateaued at approximately 30–40% of the amount which is present in the arterial inflow. This kinetic feature of bupivacaine, verified in the sheep heart, is remarkable, particularly as the ratio remained stable although systemic concentrations of bupivacaine still increased.

We cannot fully exclude the fact that the experimental design before infusion of bupivacaine may have interacted with the disposition of bupivacaine in the cardiopulmonary system. However, we do not believe that these substrates substantially affected the kinetics of bupivacaine for the following reasons: all important variables had returned to baseline levels when bupivacaine was administered. In some experiments only short-lived ultrasonic bubbles were injected, which are small vesicles prepared from galactose and filled with air. These compounds had been completely degraded before bupivacaine was infused. Other animals received inhibitors of phosphodiesterase which are pharmacologically active only for a short time. For both types of experiments each animal served as its own reference in order to compare different dosing rates or different injection sites with each other. This design has been accepted by others [17, 18]. Other experiments were undertaken in order to obtain reference values for haemodynamic variables in untreated controls or in animals which underwent mild local hyperthermia or short-term acidosis induced by carbon dioxide or lactate. Therefore, our results were obtained in three different groups of "second-hand" animals which received (a) investigational drugs, (b) local hyperthermia or acidosis for a short time or (c) were untreated controls. Therefore, we believe that these different categories of basic experiments did not have a substantial influence on the kinetics of bupivacaine as we obtained almost the same results for all animals.

We cannot definitively answer the question of whether or not other amide-linked local anaesthetics undergo high cardiac extraction in sheep. Nevertheless, from the results of the two experiments where lignocaine was used, we would expect that cardiac extraction of lignocaine does occur. However, it might be considerably lower than that of bupivacaine. Contrary to our results in sheep, elimination of bupivacaine by perfused rat hearts was negligible. The time course of bupivacaine concentrations in the medium of isolated hearts was almost identical to the course obtained for sham perfusions. The elimination half-lives largely exceeded the perfusion time in both cases. Therefore the differences between the elimination half-lives of bupivacaine in isolated hearts and those in sham controls are not important.

In contrast, bupivacaine was bound substantially to the incubated myocardial tissue of rats and sheep. However, only approximately 0.5–4 µg of ^{14}C-labelled bupivacaine was retained per gram of sliced myocardial tissue *in vitro*. This is much less than the amount which is removed by sheep hearts *in vivo*. Altogether, neither rat hearts nor sheep hearts exhibited substantial metabolism of bupivacaine *in vitro*.

In conclusion, the risk of bupivacaine in inducing fatal cardiotoxicity may be related to the pharmacokinetic properties of this compound. Bupivacaine is taken up from the blood stream by sheep hearts at a large fraction of 0.3–0.4, even at high plasma concentrations. The driving force by which bupivacaine is removed by the myocardial tissue of sheep *in vivo* was unclear until now. From the results of our *in vitro* experiments we suggest that metabolism is not important, but that binding to the tissue is a main process leading to first-pass extraction of bupivacaine. However, it is unlikely that this effect fully explains how the concentration differences are established between the aorta and coronary sinus, because the extraction ratio remained high for a long time (at lest 30 min) although bupivacaine was infused continuously and the drug load to the myocardial tissue was thus increasing. Another explanation is that bupivacaine may be drained substantially by the lymph flow of hearts because this drug is highly lipophilic and cardiac lymph flow is an important process for the myocardial tissue. But if this were true, we would expect that this effect should also be detected in the lung.

Acknowledgements

The study was supported by a grant from the Deutsche Forschungsgemeinschaft Fo 154/1-2. ^{14}C-labelled bupivacaine was a generous gift from Astra, Sődertalje, Sweden.

SHORT COMMUNICATIONS

Nitrous oxide produces a non-linear reduction in thiopentone requirements

T. KATOH AND K. IKEDA

Summary

We studied 88 healthy, ASA I patients (aged 20–45 yr), to determine if nitrous oxide affects thiopentone requirements for achieving 50% probability of no movement in response to verbal commands ($C_{P,50}$). Patients were allocated randomly to one of four nitrous oxide concentration groups (0%, 20%, 40% and 60%). Patients in each group were also allocated randomly to receive predetermined target plasma concentrations of thiopentone. Computer-controlled continuous infusion was used to maintain the target plasma thiopentone concentration, and this concentration was held constant for 6 min to ensure equilibration. The $C_{P,50}$ value of thiopentone in the absence of nitrous oxide was 14.8 μg ml^{-1}. The reduction in $C_{P,50}$ by nitrous oxide was non-linear, and the interaction coefficient between nitrous oxide and thiopentone was significantly smaller than zero ($P = 0.0274$), indicating that nitrous oxide antagonized the ability of thiopentone to prevent response to verbal commands. (*Br. J. Anaesth.* 1996; **77**: 265–267)

Key words

Anaesthetics gases, nitrous oxide. Anaesthetics i.v., thiopentone. Potency, anaesthetic.

General anaesthesia is often performed with a combination of inhalation and i.v. anaesthetics. When nitrous oxide is used in combination with thiopentone alone, intraoperative awareness is sometimes observed [1]. After a single dose of thiopentone, blood concentrations decrease exponentially. However, because of hysteresis between blood and brain concentrations, blood concentration is not a good predictor of brain concentration, and thus bolus administration of thiopentone does not permit its interactions with other drugs to be evaluated accurately. By using a pharmacokinetic model-driven computer-controlled infusion pump, it is possible rapidly to achieve and maintain a constant plasma concentration of thiopentone. Blood concentrations obtained while maintaining the plasma concentration stable can be used to undertake studies on the interactions between nitrous oxide and thiopentone. The aim of this study was to assess accurately the effects of nitrous oxide on the plasma concentration of thiopentone required to achieve a 50% probability of no movement in response to verbal commands ($C_{P,50}$).

Methods and results

After obtaining the approval of the local Ethics Committee and informed consent, we studied 88 patients of both sexes, ASA I, aged 20–45 yr, undergoing elective surgery. Patients did not receive premedication. An arterial cannula was inserted in the radial artery for blood sampling.

The 88 patients were allocated randomly to one of four groups. Patients in group 1 received no nitrous oxide, while those in groups 2, 3 and 4 received end-tidal concentrations of 20%, 40% and 60%, respectively. Patients in each group were also allocated randomly to receive predetermined target plasma concentrations of thiopentone. Thiopentone was infused using a computer-controlled infusion pump. Pharmacokinetic simulation and infusion algorithms made it possible rapidly to obtain and then maintain the target plasma concentration. The microcomputer was programmed with the thiopentone kinetic parameter set reported by Avram, Krejcie and Henthorn [2].

In group 1, patients breathed 100% oxygen throughout the study. In groups 2, 3 and 4, nitrous oxide was administered to achieve end-tidal concentrations of 20%, 40% and 60%, respectively. All patients breathed through a face mask connected to a semiclosed anaesthetic circuit. Concentrations of nitrous oxide, carbon dioxide and oxygen were measured continuously using an infrared anaesthetic gas analyser (Capnomac Ultima, Helsinki, Finland). In groups 2, 3 and 4, nitrous oxide was introduced after the patient had breathed 100% oxygen for 3 min. In group 1, thiopentone infusion was started 3 min after the start of oxygen, and in groups 2, 3 and 4, thiopentone infusion was started after the specified end-tidal nitrous oxide concentration had been maintained for more than 5 min. Infusion was regulated to maintain the target thiopentone concentration. At 5 min after the start of infusion, blood samples were obtained for measurement of thiopentone concentrations. At 10 min, patients were

TAKASUMI KATOH, MD, KAZUYUKI IKEDA, MD, FRCA. Department of Anaesthesiology and Intensive Care Medicine, Hamamatsu University School of Medicine, 3600 Handa-cho, Hamamatsu, 431-31 Japan. Accepted for publication: March 6, 1996.

asked to open their eyes and blood samples were obtained. The patient's response to verbal command was recorded as positive or negative, with slight movement of the eyelids considered a negative response.

Plasma was separated immediately from blood and total plasma thiopentone concentrations were measured as soon as possible, usually within 4 h, using a high pressure liquid chromatographic assay with a sensitivity of 100 ng ml^{-1}. To ensure that stable plasma concentrations of thiopentone was maintained throughout infusion, the 5-min samples were compared with the 10-min samples. The mean concentration of the 5-min and 10-min samples was used for statistical analysis only if the concentration in the 5-min sample was within ±30% of that in the 10-min sample.

STATISTICAL ANALYSIS

The $C_{P,50}$ of thiopentone, and its reduction by nitrous oxide, were evaluated using the following multiple independent variable logistic regression model:

$$P(\text{no response}) = \frac{1}{1+e^{-Z}}$$

$$Z = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_{12} X_1 X_2$$

where $X_1 =$ measured plasma concentration of thiopentone, $X_2 =$ end-tidal nitrous oxide concentration, $\beta_0 =$ regression intercept constant, $\beta_1 =$ coefficient for thiopentone, $\beta_2 =$ coefficient for nitrous oxide and $\beta_{12} =$ coefficient for the product of the measured thiopentone and end-tidal nitrous oxide concentrations (interaction coefficient). The likelihood ratio test was applied to determine the independent variables to be removed from the model. $C_{P,50}$ for a given end-tidal nitrous oxide concentration was determined by setting the probability of no response to 0.5 and solving for thiopentone concentration as a function of the end-tidal nitrous oxide concentration as follows:

$$X_1 = \frac{-(\beta_0 + \beta_2 X_2)}{\beta_1 + \beta_{12} X_2}$$

Although a total of 88 patients were enrolled in the study, nine patients were excluded from the subsequent analysis because the measured thiopentone concentrations before and after verbal command were not within ±30%. In addition, one patient was eliminated from the study because of severe excitatory phenomena and vomiting. Thus the results of 78 patients are presented. This group included 48 men and 40 women with a mean age of 36 (range 20–45) yr and mean body weight of 56 (42–78) kg.

The logistic model was fitted to 78 data sets of observed response, measured plasma thiopentone concentration and end-tidal nitrous oxide concentration. The $C_{P,50}$ of thiopentone in the absence of nitrous oxide was 14.8 µg ml^{-1}. None of the three independent variables was removed from the model by the likelihood ratio test. The interaction coefficient β_{12} was significantly smaller than zero ($P =$ 0.0274). The reduction in the $C_{P,50}$ of thiopentone by nitrous oxide is presented in figure 1.

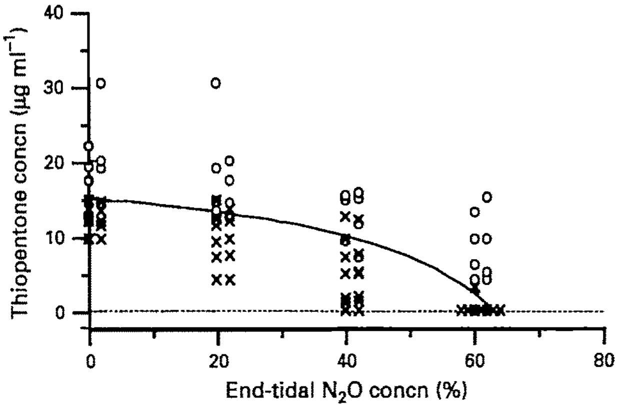

Figure 1 Plasma thiopentone concentration *vs* end-tidal nitrous oxide concentration for each patient. Each point represents the positive (movement (×)) or negative (no movement (0)) response for an individual patient. The line represents the maximum likelihood (logistic regression) solution for the reduction in $C_{P,50}$ of thiopentone by increasing concentrations of nitrous oxide.

Comment

The $C_{P,50}$ of thiopentone alone was found to be 14.8 µg ml^{-1}. The $C_{P,50}$ value determined in this study was almost identical to that obtained by Hung and colleagues using a similar technique [3]. The effect of nitrous oxide on the $C_{P,50}$ of thiopentone has not been documented previously. Nitrous oxide, however, has been shown to reduce the MAC_{awake} for isoflurane in a dose-dependent manner, with the MAC_{awake} reported as 67% [4]. Thus, 20%, 40% and 60% nitrous oxide should correspond to MAC_{awake} fractions of 0.3, 0.6 and 0.9, respectively. In a previous study, when nitrous oxide was administered together with isoflurane at an end-tidal concentration of 40%, the MAC_{awake} value for the combination of isoflurane and nitrous oxide was 18 (SEM 4)% greater than the value expected for simple additivity of the two agents [4]. This result indicates that the two anaesthetics are antagonistic with regard to this effect. We found that nitrous oxide reduced the $C_{P,50}$ in a dose-related manner. The interaction coefficient between thiopentone and nitrous oxide was significantly smaller than zero, indicating that nitrous oxide had a non-linear effect on reducing thiopentone requirements and that thiopentone requirements were greater than would be expected for simple additivity. Nitrous oxide appears to antagonize the ability of thiopentone to prevent responses to verbal commands. This may be caused by the ability of nitrous oxide to stimulate sympathetic activity. Hankala and co-workers found EEG evidence that nitrous oxide opposed the central nervous system depression produced by isoflurane [5]. Although there have been no reports that nitrous oxide reverses the central nervous system depression produced by thiopentone, this may offer a possible explanation for our findings.

In conclusion, nitrous oxide produced a non-linear reduction in thiopentone requirements for preventing response to verbal commands and the reduction was smaller than would be expected for simple additivity at low concentrations.

Evaluation of two warming systems after cardiopulmonary bypass

E. L. Janke, S. N. Pilkington and D. C. Smith

Summary

We have compared the Thermomat electric undermattress (JMW Systems, Edinburgh, UK) and the Bair Hugger (Augustine Medical, Courtelary, Switzerland) forced-air warming blanket in 30 adult patients after cardiac surgery. All patients were warmed to an oesophageal temperature of 38 °C before termination of cardiopulmonary bypass (CPB); those with oesophageal temperatures < 35.5 °C at skin closure were allocated randomly to be rewarmed in the intensive care unit either on the Thermomat ($n = 15$) or under the Bair Hugger blanket ($n = 15$), at their highest settings. Oesophageal and lateral thigh skin temperatures were recorded every 15 min for 4 h. There was a significantly faster increase in core temperature (0.5 *vs* 0.75 °C h^{-1}; $P < 0.0002$) and skin temperature (0.86 *vs* 1.3 °C h^{-1}; $P < 0.001$) in the Bair Hugger group. However, there was no difference in the number of patients who reached a core temperature of 36 °C (15 Bair Hugger, 14 Thermomat) or 37 °C (11 Bair Hugger, seven Thermomat), or in the number of patients who reached a skin temperature of 37 °C in 4 h (four Bair Hugger, one Thermomat). Twelve patients in the Bair Hugger group reached a skin temperature of 36 °C compared with two in the Thermomat group ($P < 0.001$). The Bair Hugger warmed faster than the Thermomat both centrally and peripherally, and warmed more patients to a core temperature of 37 °C in 4 h, but did not reduce the time to tracheal extubation or alter important clinical aspects of postoperative course. (*Br. J. Anaesth.* 1996; **77**: 268–270)

Key words

Temperature, monitoring. Monitoring, temperature. Equipment, warming devices. Surgery, cardiovascular. Heart, cardiopulmonary bypass.

A decrease in temperature after cardiopulmonary bypass (CPB) is common; adequate rewarming may be difficult to achieve despite active intraoperative warming [1–3]. Residual hypothermia may delay drug clearance, impair coagulation and cause haemodynamic instability [4, 5]. We hypothesized that a forced-air convective system, such as the Bair Hugger, is a better means of warming adult patients after CPB in the intensive care unit (ICU) than a heated electric undermattress such as the Thermomat, which warms by conduction. This study was designed to determine if the Bair Hugger warming blanket is more effective than the Thermomat warming mattress in rendering adult patients normothermic who are hypothermic on arrival to the ICU after CPB.

Methods and results

After obtaining approval from the hospital Ethics Committee, we studied 30 adult patients with normal to moderately impaired left ventricular function undergoing hypothermic CPB for elective cardiac surgery. Premedication comprised a benzodiazepine and opioid; anaesthesia was induced with fentanyl 20–30 µg kg^{-1}, and midazolam 1–10 mg or thiopentone 25–100 mg, or both, and pancuronium was administered to provide neuromuscular block. Patients' lungs were ventilated with oxygen-enriched air (± isoflurane before bypass) with a heat–moisture exchanging filter; propofol 1–2 mg kg^{-1} was infused during CPB to maintain anaesthesia. Oesophageal (heart) and nasopharyngeal (brain) temperatures (Mon-a-therm General Purpose Critical Care Temperature Probes, Mallinckrodt Medical, Inc., Northampton, UK) were measured continually during operation. All patients were warmed actively to both oesophageal and nasopharyngeal temperatures of at least 38 °C before termination of bypass, using warm perfusion and a heated water mattress. Oesophageal temperature was used thereafter to measure core temperature, consistent with routine practice in our ICU. Patients with oesophageal temperatures < 35.5 °C at skin closure were allocated randomly to be rewarmed in the ICU either covered with a sheet and a cotton blanket, lying on the Thermomat mattress set at 41 °C (its highest setting) or using the Bair Hugger set on "high" (43 °C), placed directly on the patient and covered with a sheet and cotton blanket. Core and peripheral (skin, lateral aspect of thigh; Mon-a-therm, Mallinckrodt Medical, as above) temperatures were recorded every 15 min for 4 h or until normothermia (oesophageal temperature 37 °C) was achieved. The presence or absence of gross shivering, blood loss in the first 4 h and time to extubation were recorded. Sample size was determined by power analysis; 30 patients were required to detect a clinically relevant difference (one method warming patients to 36 °C core temperature 1 h faster than the other) with an 80% power of achieving a statistically significant result at the 5% level. The two sample *t* test was used to compare

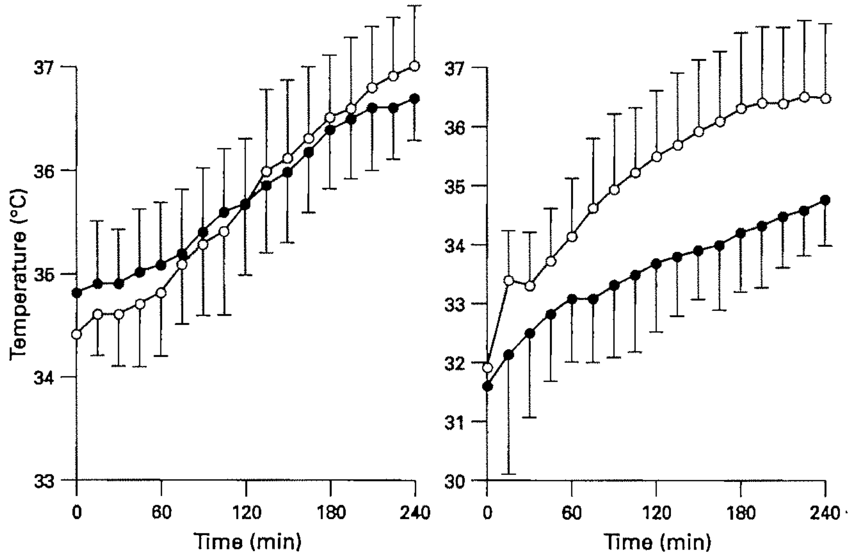

Figure 1 Comparison of changes in mean core temperature (left) and mean skin temperature (right) between the Bair Hugger group (○) and Thermomat (●) groups (mean, SD).

parametric data and rates of oesophageal and skin warming in each group. The chi-square test with Yates' correction was applied to compare non-parametric data. $P < 0.05$ was considered statistically significant.

There were no differences between the two groups in patient characteristics, treatment with inotropes or vasodilators, or incidence of postoperative shivering (two of 15; 13%). There was no difference in mean oesophageal temperature (34.8 °C for the Thermomat group, 34.4 °C for the Bair Hugger group; $P = 0.051$) or mean skin temperature (31.6 °C for the Thermomat group, 31.9 °C for the Bair Hugger group; $P = 0.5$) on arrival in the ITU, or a difference in core-to-skin temperature gap (3.2 °C for the Thermomat group, 2.5 °C for the Bair Hugger group; $P = 0.1$).

The number of patients reaching core temperatures of 36 °C (15 in the Bair Hugger group, 14 in the Thermomat group; $0.2 > P > 0.1$) and 37 °C (11 in the Bair Hugger group, seven in the Thermomat group; $0.1 > P > 0.05$), was not significantly different. Only two patients in the Thermomat group reached a skin temperature of 36 °C compared with 12 patients in the Bair Hugger group ($P < 0.001$). There was no difference in the number of patients who reached a peripheral temperature of 37 °C within 4 h (one patient in the Thermomat group, four patients in the Bair Hugger group; $0.2 > P > 0.1$). The mean rate of core temperature increase was 0.5 °C h^{-1} for patients in the Thermomat group and 0.75 °C h^{-1} in the Bair Hugger group ($P < 0.0002$). The mean rate of increase in skin temperature was 0.86 °C h^{-1} for the Thermomat group and 1.3 °C h^{-1} for the Bair Hugger group ($P < 0.001$). A comparison of mean temperatures for each group over time is shown in figure 1.

Comment

Patients undergoing CPB are unique in that intentional systemic hypothermia occurs with an open chest cavity; for part of this time the lungs are not ventilated and the heart is actively cooled separately. Even with aggressive central and peripheral warming, there is ongoing heat loss after bypass, during wound closure and transport to the ITU. Subsequent temperature equilibration between the core and periphery may result in a decrease in core temperature, sometimes rapidly. Behavioural and physiological responses to hypothermia are often undesirable in cardiac patients and may be ablated in the ITU by residual anaesthetic agents, vasodilators, sedation and neuromuscular block. Shivering may be intentionally abolished because it increases the body's oxygen demand by 400–500% [6]; it may also promote respiratory acidosis from increased carbon dioxide production. Ordinarily, spontaneous arrhythmias are not seen until core temperature has decreased to approximately 33 °C. In patients who have had open heart surgery, ischaemia, acid–base or electrolyte abnormalities, or other co-existing factors, may contribute to myocardial irritability. Other physiological changes associated with hypothermia such as altered blood-gas transport, increased blood viscosity and mental status changes, do not occur until reductions in body temperature are extreme [4].

Conductive heat transfer occurs by direct contact between objects; in the intraoperative period, heat is lost in this way to the operating table and underlying wet sheets, cool i.v. fluids and irrigating solutions. The heat supply of a warming mattress (a conducting surface) is limited by skin conductance, temperature gradient and contact area. To prevent burns, a sheet is usually interposed between the mattress and the patient, interfering with heat transfer. Additionally, peripheral vasoconstriction may further reduce the effectiveness of a warming mattress as a heat exchanger. A warming mattress can be warmed on the bed before the patient is transferred to it, but removal of the warming mattress from under the patient can be cumbersome. However, the mattress may stay in place during most routine postoperative care in the ICU. Convective heat exchange involves the direct transfer of energy by collisions between body surface molecules and moving air molecules. Air velocity, ambient temperature and surface area are its main determinants. The forced-air warming mattresses currently available are lightweight and easy to use, although they are often partially removed or displaced in the ICU for certain aspects of care, potentially decreasing their effectiveness as a means of warming.

Although our study showed a faster rate of both core and peripheral warming by the Bair Hugger, there was no difference in the time to tracheal extubation or in the overall nature of the postoperative course between the two groups. This suggests that both a heated electric undermattress and a forced-air warming blanket are appropriate methods of warming hypothermic patients after bypass in the ICU.

Calcium homeostasis during i.v. infusion of 1.5% glycine in anaesthetized pigs

D. CHASSARD, K. BERRADA, J. P. TOURNADRE AND P. BOULÉTREAU

Summary

We have examined changes in plasma concentrations of calcium in seven anaesthetized pigs during i.v. infusion of irrigating fluid containing 1.5% glycine. Volumes infused were 875 ml at 20 min (22 ml kg^{-1}), 1475 ml at 40 min and 2075 ml at 60 min (75 ml kg^{-1}). Plasma concentrations of sodium decreased from 134.5 (SD 3.4) to 112.8 (6.7) mmol $litre^{-1}$ at 60 min and correlated with the volume of glycine infused ($r^2 = 0.73$; $P < 0.0001$). Changes in total calcium concentrations were not statistically significant. A decrease in ionized calcium concentration was observed at 40 min (1.12 (0.05) *vs* 1.24 (0.04) mmol $litre^{-1}$; $P < 0.05$) and reached 1.11 (0.05) mmol $litre^{-1}$ at 60 min ($P < 0.01$). However, when corrected for pH, this decrease was not statistically significant. These results suggest that changes in plasma concentrations of sodium rather than changes in calcium homeostasis are probably more important in the development of transurethral prostatic syndrome. Resection of the prostate or endometrium by resectoscope is a technique which requires the use of electrically inert near-isotonic solutions for irrigation. Resorption into the patient's body of a large amount of glycine-containing irrigating fluid used for these procedures has been reported [1]. This complication includes biological disturbances such as dilutional hyponatraemia and hypo-osmolality [1]. Some clinical observations suggested that hypocalcaemia could be associated with these plasma disturbances [2]. However, there has been no controlled study evaluating calcium changes during i.v. infusion of irrigating fluid. In this study, we assessed the acute effects of i.v. infusion of glycine on calcium homeostasis in anaesthetized pigs.

Methods and results

After obtaining approval from our institution's Animal Care Committee, we studied seven pigs (23–25 kg). Ketamine 8 mg kg^{-1} was given i.m. after a 12-h fast. Anaesthesia was induced with propofol 5 mg kg^{-1} i.v., sufentanil 3 µg kg^{-1} i.v. and pancuronium 0.1 mg kg^{-1} i.v., and was maintained with propofol 10 mg^{-1} kg^{-1} h^{-1}. Ventilation was adjusted to maintain an end-tidal carbon dioxide concentration of 4–5%.

A femoral vein and artery were cannulated to provide arterial pressure monitoring, arterial blood samples and a route for administration of glycine. Arterial blood samples were obtained for baseline measurements before a dose of 500 ml of 1.5% glycine (Glycocolle 1.5%, Baxter, Maurepas, France) was infused over 5 min, followed by a constant infusion of 1500 ml h^{-1} over 55 min. This corresponds to an infusion rate of 34 ml kg^{-1} during the first 20 min and 75 ml kg^{-1} over the whole study. Repeated measurements were made 20, 40 and 60 min after the beginning of the infusion of glycine. Samples of blood for measurement of ionized calcium and pH-normalized ionized calcium concentrations were obtained anaerobically into preheparinized syringes and analysed immediately using the ICA II instrument (Copenhagen, Denmark). Plasma concentrations of sodium, potassium, magnesium, calcium, chloride, urea, protein, bicarbonate and blood glucose were analysed using the Astra 8 chemistry instrument (Beckman, Schiller Park, IL, USA). Pa_{O_2}, Pa_{CO_2} and arterial pH were measured using a Radiometer ABL electrode system (Copenhagen, Denmark). The concentration of ammonia in blood was measured by the ACA III instrument (Du Pont, Wilmington, DE, USA). Osmolality was calculated using a standard formula: osmolality (mosmol $litre^{-1}$) = (sodium mmol $litre^{-1}$ × 2) + urea mmol $litre^{-1}$ + blood glucose mmol $litre^{-1}$.

Statistical significance was determined using analysis of variance (ANOVA) for repeated measures followed by Dunn's test. $P < 0.05$ was considered statistically significant. Relationships between electrolyte concentrations and volume of glycine infused were assessed using Pearson's product correlation coefficient (r) and coefficient of determination (r^2).

During the first 20 min of i.v. infusion (875 ml), there was a significant decrease in mean plasma concentrations of sodium from 134.5 (SD 3.4) to 121.2 (4.0) mmol $litre^{-1}$ ($P < 0.05$). At 40 min (1375 ml perfused), pigs demonstrated a more

marked decrease in plasma concentrations of sodium of 17 mmol ($P < 0.05$). At 60 min (1875 ml perfused), this decrease was 22 mmol (mean plasma sodium concentration 112.8 (6.7) mmol litre^{-1}) ($P < 0.001$). This decrease was correlated significantly with the volume of glycine infused ($r = 0.85$, $r^2 = 0.73$, $P < 0.0001$). A statistically significant decrease in calculated osmolality was seen at 40 min ($P < 0.05$) and 60 min ($P < 0.001$). Protein, urea, ammonia and other electrolyte concentrations, including potassium, magnesium and phosphate, did not change significantly from baseline during the study (table 1).

A 12% decrease in plasma concentrations of calcium occurred after infusion of glycine but this decrease was not significant (table 1). In contrast, ionized calcium decreased significantly at 40 min but remained greater than 1.10 mmol litre^{-1}. When ionized calcium was correlated for arterial pH, there was no significant change.

There were no statistically significant correlations between calcium, ionized calcium or pH-corrected ionized calcium, and volume of glycine infused ($r = -0.46$, -0.68, -0.54 and $r^2 = 0.21$, 0.46, 0.29, respectively) and no relationship between ionized calcium and changes in serum protein concentration.

Comment

It is generally believed that transurethral resection of the prostate syndrome (TURPS) is the results of dilutional hyponatraemia caused by the direct toxicity of glycine and by hyperammonia [1]. Recently, hypocalcaemia has been proposed in the physiopathology of TURPS [2].

Hypocalcaemia denotes low concentrations of biologically active calcium in blood. In fact, symptoms caused by altered concentrations of calcium reflect changes in the serum concentration of ionized calcium [3]. Only one case report expressed interest in the ionized calcium concentration rather than the total calcium concentration during TURPS [2].

In this study, we evaluated changes in plasma calcium concentrations during i.v. infusion of 1.5% glycine. We found no statistically significant changes in serum calcium concentrations throughout the study. However, a significant decrease in ionized calcium was noted after infusion of glycine 1475 ml over 40 min. Nevertheless, concentrations of ionized calcium were in the normal range for our laboratory and pH-normalized ionized calcium was not decreased significantly by infusion of glycine. Thus, within the limitations of our study, we found that infusion of glycine was not associated with significant disturbances in serum calcium.

Few studies have examinated calcium homeostasis during absorption of irrigating solutions such as glycine, despite the crucial role of calcium in neurological and cardiovascular function. Malone and colleagues reported a peroperative decrease in plasma calcium; further changes were not observed in the postoperative period [4]. In seven healthy volunteers, glycine 1 litre i.v. over 20 min (20 ml kg^{-1}) significantly decreased plasma concentrations of calcium [5]. A decrease in plasma calcium concentration (2.04 *vs* 2.16 mmol litre^{-1}) was also seen after 1.57 litre (22 ml kg^{-1}) of fluid absorption [6]. The clinical significance of these studies is limited as none measured pH-normalized ionized calcium.

Several events may induce acute hypocalcaemia during anaesthesia: transient hypomagnesaemia, an increase in plasma albumin concentration, administration of citrate and hyperphosphataemia are more common causes [3]. It must be remembered that the concentration of ionized calcium is dependent on arterial pH: acidosis increases and alkalosis decreases the concentration. In our study, none of these factors was present: phosphorus concentration was decreased and the decrease in plasma magnesium concentration was not statistically significant.

Volumes of glycine absorbed during TURPS are generally 500–4000 ml [1, 6]. The volumes administered in our animal study were 875 ml at 20 min and 1875 ml at 60 min (34 and 75 ml kg^{-1}). For humans weighing 60–70 kg, this corresponds to values of 2000–5000 ml. Moreover, serum concentrations of sodium were less than 120 mmol litre^{-1}, a value known to be the threshold for the development of TURPS [1]. Despite this, calcium homeostasis was not altered.

CASE REPORTS

Cardiac arrest after Caesarean section under subarachnoid block

T. J. SCULL AND F. CARLI

Summary

Cardiac arrest occurred on arrival in the recovery room after emergency Caesarean section under subarachnoid block. The patient was resuscitated successfully and recovered with no adverse effects. The current literature is reviewed and the pathophysiological mechanisms involved in the aetiology of cardiac arrest under subarachnoid block are discussed. Early use of adrenaline to treat severe bradycardia or hypotension is recommended. (*Br. J. Anaesth.* 1996; **77**: 274–276)

Key words

Anaesthesia, obstetric. Complications, cardiac arrest. Anaesthetic techniques, subarachnoid.

Subarachnoid anaesthesia is a widely practised technique for both elective and emergency procedures. It is recommended for both its efficacy and safety [1, 2]. Haemodynamic instability and cardiac arrest have been reported in healthy patients [3]. Occasional case reports [3–5] and a series of patients experiencing cardiac arrest [6] have been reported in the American literature, but there is little in the European journals. We report a case of cardiac arrest, occurring in a parturient after a Caesarean section under subarachnoid block.

Case report

A 31-yr-old Afro-Caribbean woman (weight 76 kg, height 1.68 m), ASA I, presented at term in spontaneous labour. This was her second pregnancy; her first had resulted in a vaginal delivery and the course of the second had been uneventful.

On arrival in the delivery suite she was in active labour, her cervix was dilated 6 cm and her membranes were bulging. These were ruptured and fetal monitoring, via a scalp electrode, commenced. Over the next 8 h, progress was slow, dilatation increasing to 8 cm. The baby showed signs of distress which were manifested as type 2 decelerations, and it was decided to deliver the baby by Caesarean section.

Subarachnoid anaesthesia was commenced using a 27-gauge Quinke needle with 0.75% hyperbaric bupivacaine 2 ml and preservative-free morphine 0.25 mg. Bilateral sensory block to temperature from T2 to S5 was obtained. After positioning the patient in the supine position, with left lateral wedging, Caesarean section was carried out, and a boy (3585 g) with Apgar scores of 9 at both 1 and 5 min was delivered. Arterial pressure, ECG and oxygen saturation were monitored throughout the procedure. Systolic arterial pressure was 110–120 mm Hg and heart rate 70–110 beat min^{-1}. Saline 0.9% (2 litre) and three boluses of ephedrine 5 mg were required to maintain stability. After delivery, an infusion of Syntocinon 20 u. in normal saline 1 litre was started. The duration of Caesarean section was 1 h 35 min and estimated blood loss was 700 ml. The patient's vital signs before leaving the operating theatre were: arterial pressure 110/60 mm Hg, heart rate 105 beat min^{-1} and Sp_{O_2} 96%. The patient was then transferred to the adjacent recovery room in a semi-reclined position, fully conscious, conversing and holding her baby. As monitoring was being re-established, she suddenly became unresponsive, with no palpable pulse and no respiratory effort.

Cardiopulmonary resuscitation was initiated and her trachea was intubated within 2 min. ECG revealed the initial rhythm to be ventricular fibrillation and she received four dc shocks, adrenaline 2 mg i.v., naloxone 0.4 mg i.v. and lignocaine 100 mg i.v. At 9 min after cardiac arrest her rhythm had converted to sinus tachycardia, with a strong pulse. She was then transferred to the intensive care unit.

A series of investigations was carried out to identify the cause; ECG revealed a sinus tachycardia with no acute changes, echocardiogram showed good left ventricular function (ejection fraction 55–60%), with normal valvular morphology and function. Serum electrolyte concentrations were within normal limits, except for a low serum magnesium concentration of 0.25 mmol litre^{-1} (normal 0.75–1.25 mmol litre^{-1}) obtained at the time of cardiac arrest. A CT scan revealed minimal cerebral oedema, and a ventilation–perfusion scan of the lungs was normal.

The patient's lungs were ventilated for 20 h and she remained haemodynamically stable without need of inotropic support. After tracheal extubation she was confused, with no memory of the preceding events. Her cognitive function returned to normal over the following week. Despite extensive investi-

gation, no obvious cause of the arrest was found, other than the low magnesium concentration, the aetiology of which was unclear. In the postoperative period she developed a wound infection that necessitated a prolonged hospital stay. She was discharged home 25 days after her section and remains well.

Discussion

Cardiac arrest during subarachnoid anaesthesia is an uncommon but well reported phenomenon. Bradycardia with resultant hypotension is thought to occur by two mechanisms. The first involves block of the cardioacceleratory sympathetic fibres, which may occur with a sensory block as low as T10, as it has been shown that the sensory–sympathetic differential may be up to six segments [7]. This allows unopposed parasympathetic input with a negative chronotropic effect. The other mechanism is a manifestation of decreased venous return, which may trigger reflexes mediated by caval and atrial receptors [8], and the pacemaker stretch reflex [9]. Acute reductions in venous return have also been reported to activate the Benzold–Jarish reflex with resultant bradycardia [10].

Excessive bradycardia progressing to asystole has been well documented recently [3, 4]. In some reports [3–5], patients responded promptly to atropine, ephedrine and external cardiac massage, cardiac output and consciousness being rapidly restored with no sequelae after the event. The series of patients reported by Caplan and colleagues [6], as a result of closed claims analysis, exhibited a different outcome and possibly a different pathogenesis. These patients showed marked similarities; all were young (mean age 35 yr), healthy (ASA I or II), had high sensory block, and all experienced a poor outcome; six died and seven were severely neurologically damaged. Close scrutiny of these cases implicated the use of sedation with opioids or benzodiazepines, with a resulting respiratory insufficiency, to be possible causative factors in 50 % of the cases [6, 12]. In addition, another 22 cases from closed claims analysis have recently been reported [11]. These patients had similar characteristics and outcomes to the initial series of 13. Pulse oximetry failed to demonstrate desaturation and it was concluded that "one or more circulatory mechanisms played an important role in these events."

Our patient had some factors in common with the "Caplan groups". The patient was young, haemodynamically stable, with a high sensory block, but outcome was good. Cases of cardiac arrest after subarachnoid block that required protracted resuscitation and had a good outcome are rare. Perhaps this represents a lack of reporting or indicates that a high sympathetic block in some way complicates successful resuscitation.

Detailed analysis of the closed claim cases reveals the importance of warning signs of the forthcoming arrest, usually bradycardia or hypotension in the preceding 1–2 min. Our case was in transfer to recovery during this phase, with no monitoring in place and it is therefore not possible to comment on the presence or absence of these signs.

We believe that the patient suffered a primary cardiac arrest. In the period immediately after the arrest she received treatment with i.v. naloxone, but we do not feel that respiratory depression secondary to intrathecal opioids played any aetiological role in the chain of events. It may be significant that our patient experienced the cardiac arrest shortly after repositioning had occurred. In this unit it is customary to roll the patient from side to side in order to clean the abdomen, and then to transfer the patient to the recovery area in a semi-reclined position, approximately 30° head-up. These positional changes may have resulted in alterations in venous return and triggering of the above-mentioned reflexes, causing bradycardia and hypotension. Blood loss in the presence of sympathetic block may lead to hypotension, however only 700 ml was lost over a 1–1.5-h period, and adequate replacement was achieved.

Hypomagnesaemia at the time of the arrest was the only electrolytic abnormality. This is associated with cardiac arrhythmias, and is known to prolong QT intervals [12]. In addition to cardiac signs, patients usually complain of weakness and tremors and exhibit muscle fasciculation. The patient had none of these signs or symptoms, which makes it difficult to conclude that this was the cause.

The series of patients reported by Caplan and colleagues [6] did not receive adrenaline until approximately 8 min had passed after recognition of the cardiac arrest; a perfusing rhythm was re-established within approximately 3 min of this treatment. We feel that the early use of adrenaline and the prompt resuscitative efforts were important factors in the positive outcome of our patient.

We would like to support the approach advocated by Caplan and colleagues that the potent α and β agonist adrenaline be used early in the treatment of extreme bradycardia and hypotension in patients with high sympathetic block, especially if initial treatment with ephedrine or atropine has been ineffective.

Severe systemic cholesterol embolization after open heart surgery

V. Piriou, J.-Ph. Claudel, O. Bastien, S. Ross and J.-J. Lehot

Summary

Cholesterol crystal embolization (CCE) may be triggered by various factors: intra-arterial angiographic procedures, aortic or vascular surgery, anticoagulant or thrombolytic treatments, or both. There are few previous reports of patients undergoing coronary artery bypass grafting (CABG) experiencing and therefore displaying severe systemic CCE. We describe four patients presenting, shortly after CABG, cutaneous, renal, neurological and hepatic signs related to severe CCE confirmed by skin biopsy. All patients died 11–92 days after surgery. As systemic CCE reveals severe atheromatous disease and is associated with a poor prognosis, it is advisable to avoid CABG in patients who present symptoms of CCE before surgery. (*Br. J. Anaesth.* 1996; **77**: 277–280)

Key words

Heart, coronary artery bypass. Surgery, cardiovascular. Complications, cholesterol crystal embolization.

An eroded atheromatous aorta may be a source of cholesterol crystal embolism (CCE). Embolization of atheromatous material accounts for obstruction of distal arterioles around which a foreign-body giant cell granuloma inflammatory reaction develops. The diagnosis is often delayed or unrecognized because of varying or misleading clinical signs, such as renal insufficiency, digestive or neurological symptoms, or both, or unexplained multiple-system disease [1]. Various triggering factors have been described such as intra-arterial angiographic procedures, aortic or vascular surgery, and in some cases anticoagulant or thrombolytic treatments, or both.

Patients undergoing coronary artery bypass grafting (CABG) often experience a combination of these factors: anticoagulation—before, during and after surgery—intra-arterial angiographic procedures and intraoperative aortic cross-clamping. These multiple factors could account for the acute and severe postoperative clinical and biological findings observed in the four patients described here.

Case report

From September 1992 to January 1994, four patients developed very severe and acute systemic cholesterol embolization immediately after CABG. All were male with a mean age of 67 yr (range 62–71 yr). They presented at least two risk factors for atherosclerosis, and a previous history of atheromatous disease (coronary artery disease $n = 4$, chronic peripheral arterial disease $n = 2$, carotid vascular surgery $n = 1$) (table 1). These four patients were referred to our institution for unstable angina and therefore received i.v. heparin.

A coronary angiogram was performed in all cases, 3–5 days after admission. During catheterization, patient No. 1 complained of chills and myalgias, and patient No. 3 experienced a transient cerebrovascular ischaemic accident. Multiple coronary artery disease was noted in all patients; patient No. 2 also presented severe stenosis of the left main coronary artery. Patient Nos 3 and 4 experienced a blue toe syndrome with normal peripheral pulses and renal insufficiency (serum creatinine concentration 344 μmol litre^{-1} and 281 μmol litre^{-1}, respectively) shortly after left heart catheterization, before surgery.

All patients underwent CABG 2–55 days after coronary angiogram. The immediate postoperative course was complicated in all cases: patient No. 2 presented an unstable haemodynamic status related to intraoperative myocardial infarction (confirmed by postmortem examination) which required intra-aortic balloon counterpulsation. All patients had postoperative coma, acute renal insufficiency and required haemodialysis, a highly elevated serum creatine kinase activity (patient Nos 2 and 4) and purple toes accompanied by more diffuse cyanotic mottling of the surrounding skin (livedo reticularis); peripheral pulses were normal. In addition, severe abnormalities of hepatic (elevated serum bilirubin concentration) and pancreatic (elevated serum amylase activities of 367 iu litre^{-1}) functions were observed in patient No. 1. Elevated erythrocyte sedimentation rate (ESR), transient peripheral blood eosinophilia (450 eosinophils mm^{-3}) and low C_3 complement fraction were present in patient Nos 1 and 2 (table 2, fig. 1). Systemic cholesterol embolization was confirmed in all patients by skin biopsy which showed acute inflammation with cholesterol clefts within small arterioles.

Patient management included interruption of heparin, and administration of antiplatelet agents (aspirin) and methylprednisolone 80–120 mg day^{-1}.

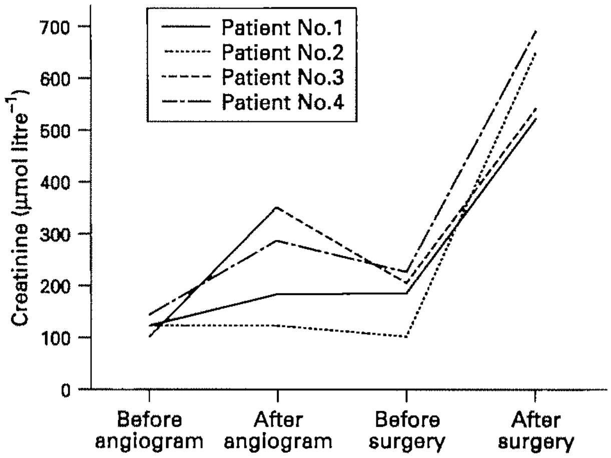

Figure 1 Serum concentrations of creatinine before and after coronary angiogram and surgery.

With this treatment, clinical and biological improvements occurred in patient Nos 1 and 3: weaning from haemodialysis and neurological improvement (normal consciousness although both had persistent hemiplegia). However, this treatment failed in patient Nos 2 and 4. All patients died within 11–92 days after surgery: patient No. 1 died from mesenteric infarction, patient Nos 2 and 4 from sudden death, and patient No. 3 from a cerebrovascular accident.

Discussion

Embolic migration of cholesterol crystals has been commonly accepted after experimental work carried out by Flory [2] and Snyder and Shapiro [3], in addition to pathological studies [4]. Cholesterol crystals obstruct 100–250 µm size arterioles. As their elimination occurs very slowly, a local foreign-body type inflammation develops, completing arteriolar obstruction. Cholesterol crystals may be released into the vascular lumen in response to rupture of the atherosclerotic plaque related to intraplaque haemorrhage or confined dissection.

CCE occurs in patients with diffuse atherosclerosis and multiple vascular risk factors (high cholesterol concentration, diabetes, tobacco abuse, hypertension) exposed to a triggering agent [5]. This diffuse embolization of atheromatous material may therefore be responsible for various clinical manifestations including: "blue toes syndrome" together with normal peripheral pulses associated with livedo reticularis of the lower limbs; renal insufficiency with severe arterial hypertension; digestive or neurological symptoms, or both; or even "fever of an unknown origin", therefore mimicking diffuse vasculitis [1] or infective endocarditis. Diagnosis may be very difficult [6] and this complications has to be borne in mind by practitioners. The onset of such clinical features is usually insidious, although acute and severe clinical manifestations after cardiac angiography have been reported [7]. Pathological [4] and clinical observations [8] support the existence of such triggering factors. Thus angiographic procedures (aortography, left heart catheterization), aortic and vascular surgery have commonly been related to the occurrence of CCE [9].

In the literature, angiographic procedures accounted for 50% of cases of CCE [10, 11]; the mean delay between the invasive procedure and symptoms was 13.5±21 days (range 1 h to 3 months). Guidewire and catheter manipulations injure the endothelium and therefore dislodge soft cholesterol material.

Aortic surgery was responsible for 9% of CCE cases published until 1988 [10, 11], but this has since reached 18% among published cases. Aortic surgery was always preceded by an angiographic procedure; aortic cross-clamping and also incision of the artery releases the atheromatous material into the bloodstream [12].

Anticoagulant therapy as a triggering factor of

CCE was first suggested in 1961 by Feder and Auerbach [13]. They reported six cases of "purple toes" with normal peripheral pulses occurring 3–8 weeks after introduction of anticoagulant treatment. Anticoagulant treatment (heparin or antivitamin K, or both) was given in 19% of published case reports [10, 11]. These medications are often associated with another triggering factor, in most cases an angiographic procedure [5, 7, 9, 14]. There are several case reports in the literature [1, 5, 13–16] in which anticoagulant therapy was the sole triggering factor. However, postmortem studies [4] failed to show any difference in the atheroembolic rate according to whether or not anticoagulants were given. This complication seems rare in view of the large number of patients treated.

Thrombolytic therapy was suspected to be an atheroembolism triggering factor as early as 1976 by Spangen and colleagues [17], who observed worsening renal function after i.v. streptokinase therapy. The first well documented case was described in 1979 and involved a patient treated with streptokinase for severe pulmonary embolism [18]. Since then, some cases indicating thrombolytic therapy as the triggering factor for CCE have been reported. In several cases, this therapy was associated with an angiographic procedure [19]; thrombolytic therapy was the sole triggering factor in other cases [20–24]. The underlying pathophysiological mechanism by which anticoagulant and thrombolytic therapy induces CCE is uncertain. Most authors [15, 18] agree that these medications lyse the platelet–fibrin protective thrombi covering ulcerated atheromatous plaques which may expose atheromatous material to the circulation.

Patients requiring cardiac surgery are at high risk of developing CCE [25, 26]. These patients with an atheromatous aorta are at risk of the main triggering factors, such as left heart catheterization, aortic cannulation and cross-clamping, and anticoagulant therapy before, during and after surgery. Severe central nervous system complications after cardiac surgery, as described in our patients, have been described widely [27]. These complications are usually related to haemodynamic (e.g. severe intraoperative hypotension) or embolic (left ventricular mural thrombus, atrial fibrillation, air embolism) events.

Severe systemic atheromatous embolization after cardiac catheterization has been described during procedures which are often long and difficult, requiring prolonged manipulations and numerous catheter changes within a severely diseased aorta [7, 28]. The sudden occurrence of clinical features seems to be related to massive embolization of atheromatous fragments dislodged by catheters. Therefore, aortic cross-clamping and canulation could be responsible for similar findings. By studying embolic signals with transcranial Doppler during cardiopulmonary bypass for coronary artery revascularization, Barbut and colleagues [29] showed that all patients ($n = 20$) displayed embolic signals. Most have been recorded during removal of aortic cross clamps (34%) and partial occlusion clamps (24%).

In addition to systemic CCE, atheromatous embolization to the distal coronary circulation may complicate CABG, and be responsible for intraoperative myocardial infarction and death, as experienced in patient No. 2. In a series of 4095 CABG, Keon, Heggtveit and Leduc [30] reported nine deaths (0.22%) related to atheromatous embolization into the coronary microcirculation. Moreover, among 175 patients who were re-operated on after a first CABG, four patients (2.29%) died from intraoperative massive myocardial infarction after atheroembolization of the distal coronary circulation. The atheroemboli were deemed to have originated from ulcerative atherosclerotic lesions in the aortic root at the ostia of the coronary arteries or vein grafts, or both, from coronary endarterectomy sites, or from mechanical disruption of plaques in the major epicardial coronary arteries during intraoperative manipulation of the heart. The higher rate of atheromatous embolic complications in patients undergoing repeated CABG is probably related to more severe atherosclerosis with soft mushy atheroma in old vein grafts.

Even though some investigators reported clinical and biological improvements with steroid therapy [1, 8, 31] or pentoxifylline [32], severe systemic CCE has a poor prognosis. The treatment is usually symptomatic, including renal and haemodynamic support.

In patients with severe aortic lesions, transoesophageal echocardiography led surgeons to modify their technique using an alternative cannulation site, hypothermic circulatory arrest [33], exploration and debridement of the aortic arch [34] or resection and graft replacement of the involved aortic segment [35]. Recently, Katz and colleagues [34] studied 130 patients undergoing open heart surgery and examined atherosclerotic lesions in the aortic arch using transoesophageal echocardiography (TOE). The severity of aortic atheromatosis was the only predictor of stroke. Ribakove and colleagues [33] found similar results, demonstrating that intraoperative clinical evaluation of aortic artheromatous disease by surgical palpation alone is not predictive of embolic stroke. Other observations revealed that TOE may demonstrate atheromatous plaques of the aortic arch involved in cholesterol embolization [36, 37] and so detect patients with a high risk of CCE before surgery. Wareing and colleagues [38] have proposed performing ascending aortic replacement or carotid endarterectomy to decrease the stroke rate after cardiac surgery in patients in whom atheromatous plaques were discovered by intraoperative ultrasonic scanning. Other studies [39, 40] have shown that intraoperative echography during cardiac surgery was able to predict patients with a high cerebral complication rate in relation to different stages of atheroma in the ascending aorta.

However, symptoms related to CCE must be sought before CABG: renal insufficiency after left heart catheterization associated with eosinophilia, blue toes syndrome and livedo reticularis. These symptoms indicate the need for a skin or muscular biopsy. Histological confirmation is essential for diagnosis and may help to age the different lesions.

When CCE is confirmed, we believe that CABG is contraindicated because of the poor prognosis of cardiac surgery.

Modulation of recombinant invertebrate $GABA_A$ receptors by isoflurane: effects of a point mutation in the M2 domain

M. D. Edwards*, R. M. Jones and G. Lees
Department of Anaesthetics, Imperial College of Science, Technology and Medicine, (St Mary's Hospital Medical School) London

GABA is the most important inhibitory transmitter in the mammalian brain. The $GABA_A$ receptor is an aggregate of 5 subunits which form an integral anion channel. This receptor is modulated at clinical concentrations, by a broad range of anaesthetic drugs [1] which displace radiolabelled probes, like picrotoxinin or *t*-butyl-bicyclo-phosphoro-thionate (TBPS), from a putative site in the ion channel [2]. A point mutation (Fig 1A) in the M2 (transmembrane) helix, which lines an invertebrate chloride channel, confers insensitivity to the $GABA_A$ antagonist, picrotoxinin [3]. We have examined anaesthetic sensitivity of both wild-type (WT) and mutant (Mut) forms of this *Drosophila* RDL subunit.

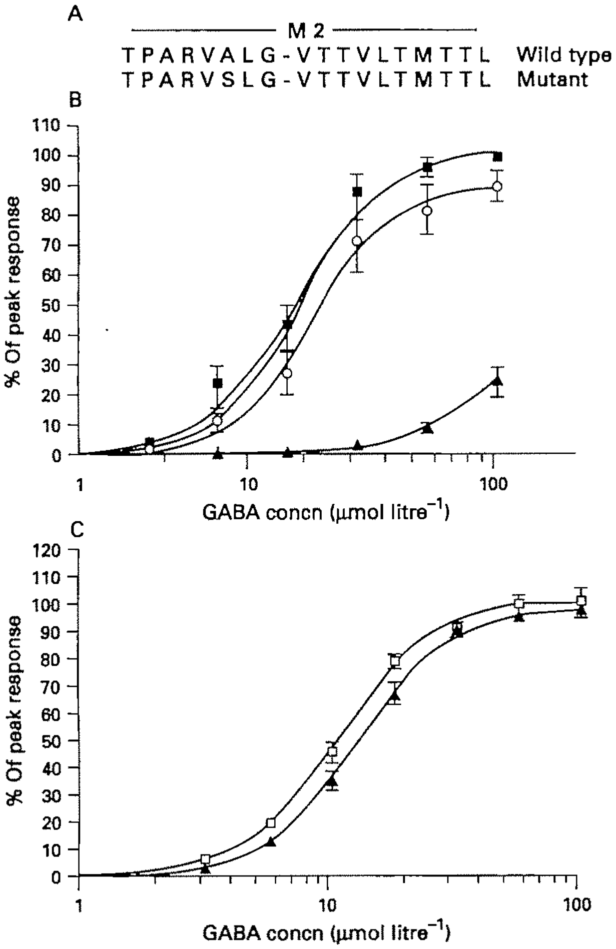

Figure 1 A: Amino-acid single letter code for the m2 region depicting the point mutation (A = alanine, S = serine). B: Effect of picrotoxin 10 μmol litre^{-1}. (■), Before picrotoxin, (○), mutant+picrotoxin, (▲), wild type+picrotoxin ($n = 6$). C: Enhancement of GABA responses by mutant+isoflurane 700 μmol litre (□), and control (▲).

cDNA samples (Cornell University) were transcribed *in vitro*, then expressed in *Xenopus* oocytes using standard techniques [3]. Ion channels were examined 1 to 5 days later using two-electrode voltage-clamp. GABA was applied for 5–15 s by throughput perfusion (approx. 10 ml min^{-1}). Sigmoid log concentration-response curves were fitted by non-linear regression to a three term logistic function before and after equilibration with drugs. Statistical assessment of pharmacological results was by two-tailed Student's *t* test, where appropriate.

WT and Mut currents reversed at −28.4 (SE 0.48; $n = 3$) mV and −28.6 (SE 2.69; $n = 4$) mV, respectively (consistent with a chloride current in the oocyte) and were both absolutely insensitive ($n = 4$/subunit) to 100 μmol litre^{-1} bicuculline ($P > 0.2$). We confirmed the relative insensitivity of the mutant channel to picrotoxin 10 μmol litre^{-1} (Fig 1B: the parallel right shift and depression (by 10%) of the maximal current suggest a "mixed" blocking action.

The point mutation reduced the relative potency of picrotoxin (at the GABA EC_{20}) by about sevenfold. Isoflurane (700 μmol litre^{-1}) reversibly enhanced subsaturating GABA currents by increasing the affinity of GABA for both the WT (not shown) and Mut receptors (Fig 1C). Dose–response curves were shifted left in a parallel fashion. Isoflurane modulated the GABA EC_{50} by 0.85×(95% CI 0.78–0.93) for the WT and 0.82×(0.76–0.88) for the Mut (statistically indistinguishable; $n = 11–13$ for each point on curves).

Isoflurane enhanced chloride currents through a "primitive" invertebrate GABA receptor. A point mutation in the putative ion channel domain did not modify anaesthetic sensitivity.

Effect of etomidate on the mass response of cells of cortical lamina V evoked by antidromic activation in the urethane-anaesthetized rat

R. H. ARNOTT* AND A. ANGEL
Department of Biomedical Science, The University of Sheffield, Sheffield

Etomidate (Hypnomidate) alters the evoked response of the somatosensory, dorsal column pathway at a site different from that affected by other agents such as urethane, halothane or thiopentone. Unlike these agents, etomidate causes perturbation in evoked behaviour at the level of primary somatosensory cortex (SI) [1], whereas the vast majority of other anaesthetics impair transmission of information through the ventrobasal thalamus [2]. By measuring the antidromically-evoked mass response of cell bodies of cortical lamina V, these experiments attempted to determine where etomidate was effective in modulating the excitability of these cortical output neurons.

Twelve rats (Sheffield strain, 190–210 g) were anaesthetized with urethane 1.25–1.5 g kg^{-1} administered i.p. A stimulating electrode was placed in the pyramidal tract and square wave pulses of 50-μs duration and 100-V amplitude, sufficient to cause supramaximal stimulation, were administered at a frequency of 1 Hz. The surface mass evoked response was recorded via a silver bead electrode placed on the exposed primary somatosensory cortex.

Pyramidal tract stimulation evoked stereotyped surface mass responses: a rapidly rising wave of surface positivity that commenced at a post-stimulus latency of approximately 1 ms, rose to a peak of approximately 2 mV at 2 ms and then decayed rapidly, crossing the initial baseline at approximately 2.8 ms. Results from previous experiments [2] suggest that pyramidal tract stimulation causes the activation only of cell bodies at depths corresponding to anatomical lamina V. It is therefore suggested that the surface mass response results from the synchronous firing of cortical lamina V cells in response to depolarization of their efferent axons.

Administration of increasing doses of etomidate (1, 2, 5, 10, 20 mg kg^{-1} i.p.) had no significant effect on the latency nor the amplitude of the mass response evoked by supramaximal pyramidal tract stimulation.

These results suggest that etomidate, which alters the behaviour of the dorsal column pathway at the level of the cortex, does not cause this alteration by reducing the responsiveness of cells of cortical lamina V. It is suggested, therefore, that the changes caused by etomidate in both the mass cortical evoked response and the evoked response of single cells of the cortical laminae result from an alteration in cortical behaviour at a site upstream of cortical lamina V cell bodies. Further experiments will be directed at investigating the effects of etomidate on the electrical behaviour of cortical cells which have synaptic connections with pyramidal cells of cortical lamina V.

Is glutamate release from rat cerebrocortical slices opioid receptor subtype selective?

B. NICOL, D. J. Rowbotham and D. G. Lambert
University Department of Anaesthesia, Leicester Royal Infirmary, Leicester

We have previously shown that morphine inhibits glutamate release from rat cerebrocortical slices [1], but there are conflicting reports as to specific subtypes involved [2, 3]. We have therefore examined the effects of the following selective agonists on glutamate release, D-Ala^2, *N*-Me-Phe^4, Gly^5-ol (DAMGO μ), [D-Pen^{2,5}]-enkephalin (DPDPE δ), ICI-199441 (κ) and spiradoline (κ).

Cerebrocortical slices (350 μm) were prepared from female Wistar rats (200–250 g). Immediately after suspension in oxygenated (95% oxygen, 5% carbon dioxide) Krebs buffer pH 7.4, the slices were pipetted into a perfusion chamber as previously described [1]. Slices were perfused at 1 ml min^{-1} for 1 h, 2 ml fractions were then collected for 6 min before a 2 min pulse of 46 mmol litre^{-1} K^+ (S_1). Slices were perfused for a further 30 min in basal Krebs before the second application of K^+ (S_2). DAMGO (1 μmol litre^{-1}), DPDPE (1 μmol litre^{-1}), ICI-199441 (1 μmol litre^{-1}) and spiradoline (1 and 100 μmol litre^{-1}), were applied for 30 min between S_1 and S_2. Glutamate concentrations were measured fluorimetrically [1]. Area under the curves, and the (S_2/S_1) ratios were calculated in order to compare the control and drug-treated slices. Wilcoxon rank sum test was used to compare the control and drug-treated slices.

DAMGO (1 μmol litre^{-1}) produced a 66% inhibition of glutamate release. DPDPE (1 μmol litre^{-1}) and ICI-199441 (1 μmol litre^{-1}) were ineffective. Spiradoline at 1 and 100 μmol litre^{-1} reduced glutamate release by 61% and 90% respectively (table 1).

These data suggest a role for μ and possibly κ agonists in the control of glutamate release and implicate these opioid subtypes as potential targets for neuroprotective therapy.

Different *in vitro* effects of aqueous or lipid etomidate preparations on neutrophil respiratory burst

M. LEUWER, D. SCHEINICHEN*, J. F. HEINE*, K. JAEGER*, L. ARSENIEV AND S. PIEPENBROCK*
Department of Anaesthesiology and Department of Haematology, Hannover Medical School, Hannover, Germany

Both propofol and its lipid carrier 10% Intralipid showed a concentration-related inhibition of neutrophil respiratory burst (RB) *in vitro* [1]. Because no statistically significant differences

Table 2 Results (mean (SD)) of the respiratory burst (RB) inhibition (%)

Etomidat-Lipuro	10 µg ml^{-1} (1)	100 µg ml^{-1} (2)
RB inhibition (SD)	83.80 (6.34)	96.93 (1.75)
Hypnomidate	10 µg ml^{-1} (3)	100 µg ml^{-1} (4)
RB inhibition (SD)	1.17 (2.20)	6.34 (4.40)
Intralipid 10%	0.6 µl ml^{-1} (5)	6 µl ml^{-1} (6)
RB inhibition (SD)	5.02 (4.85)	90.60 (4.24)
Lipofundin MCT 10%	0.6 µl ml^{-1} (7)	6 µl ml^{-1} (8)
RB inhibition (SD)	11.3 69.57)	86.80 (7.20)

between 10% Intralipid alone and propofol were found the effect of parenteral lipid solutions remained to be clarified. Since propofol is available only in a lipid carrier preparation we studied the effect of an aqueous (Hypnomidate) and a lipid (Etomidat-Lipuro) etomidate preparation on RB *in vitro*. Additionally, the effects or equivalent concentrations of the lipid carrier solutions of etomidate (Lipofundin MCT) and of propofol (Intralipid 10) alone were studied.

After Ethics Committee approval venous blood was drawn from 20 healthy blood donors. Leucocytes were obtained as supernatant by using 1 g sedimentation. The anaesthetic (10 µg ml^{-1} plasma) [2] and 10-fold anaesthetic plasma concentrations of both etomidate preparations were investigated. Additionally, two different Intralipid concentrations (0.6 and 6 µl ml^{-1}) corresponding to its plasma concentrations with anaesthetic and 10-fold anaesthetic propofol concentrations and the same concentrations of lipofundin were studied. The influence of these drugs on RB was measured via flow cytometry by the intracellular oxidation of dihydrorhodamine-123 to the fluorescent rhodamine-123 [3]. The percentage inhibition was calculated in comparison with the positive control response (RB after full stimulation by phorbol myristate acetate in the absence of the tested drugs). Prestimulation of neutrophils was quantified by negative controls (RB without stimulation by phorbol myristate acetate and without drugs). Propidium-iodide viability discrimination was also carried out. Student's *t*- or Wilcoxon test were applied for the evaluation of differences ($P < 0.05$).

The results are presented in table 2. The statistically significant differences are as follows: (1) *vs* (2) ($P < 0.05$), (1) *vs* (3) ($P < 0.001$), (2) *vs* (4) ($P < 0.001$), (5) *vs* (6) ($P < 0.001$), (5) *vs* (7) ($P < 0.05$), (7) *vs* (8) ($P < 0.001$).

In contrast with the lipid preparation, the aqueous etomidate preparation showed an almost irrelevant and not significantly dose-related RB inhibition. Thus the significant effect of the lipid preparation may be due to the lipid carrier alone. Equivalent concentrations of different lipid solutions seem to suppress phorbol myristate acetate stimulated RB by a similar magnitude.

Key words
Anaesthetics, i.v., etomidate.

Onset of neuromuscular block at the larynx using video imaging

K. J. GIRLING, M. S. QURAISHI AND R. P. MAHAJAN
University Department of Anaesthesia and Department of Otolaryngology Queen's Medical Centre, Nottingham

The onset of neuromuscular block at the larynx has been described previously by Donati and co-workers who measured pressure generated in the cuff of a tracheal tube placed between the vocal cords on superficial stimulation of the recurrent laryngeal nerve [1]. We used video imaging to assess the onset of neuromuscular block at the vocal cords and compared this with the onset of block at the adductor pollicis.

Fourteen (ASA I or II) patients scheduled to undergo elective ENT surgery were recruited. None received premedication and anaesthesia was induced with propofol 2–3 mg kg^{-1} supplemented with alfentanil 10 µg kg^{-1} and maintained with a propofol infusion at 10–12 mg kg^{-1} h^{-1} for the duration of the study period. The patients were allowed to breathe oxygen spontaneously via a laryngeal mask until they became apnoeic when ventilation was supported manually. The left arm was secured for neuromuscular monitoring and an accelerometer (Tof-guard, Biometer, Odense, Denmark) was attached to the wrist. An Olympus P3 fibre-optic scope was introduced via the laryngeal mask and the cords visualized. The recurrent laryngeal nerve was stimulated using a previously described technique [1]. The first seven patients (group 1) received a train-of-four stimulus at 15-s intervals and the subsequent seven (group 2) a single stimulus at 10-s intervals. The movement of the vocal cords to stimuli at 50, 55 and 60 mA was determined and a 60 mA stimulus was applied to the recurrent laryngeal nerve for the remainder of the study. Vecuronium 0.1 mg kg^{-1} was then administered via the i.v. cannula and the responses of the vocal cords to stimulation were recorded on a video tape and the thumb twitch height was stored by the accelerometer. The video tape images were later digitized and the angle between the cords was measured (SigmaScan for Windows, Jandel Scientific) at rest and at the point of maximal contraction until cord movement ceased. The degree of block at the hand and larynx was compared at each time interval using ANOVA and Student's *t*-test.

Table 3 Time to onset of maximal block at the hand and larynx (s) in the two groups

	Train-of-four		Single twitch	
Patient	Hand	Larynx	Hand	Larynx
1	150	165	130	140
2	165	180	290	240
3	135	150	180	210
4	105	165	160	150
5	165	135	130	160
6	210	225	190	110
7	120	135	190	210

There was no difference in the mean time to onset of maximum block at the larynx and the hand using single twitch or train-of-four responses (table 3). The technique did reveal a difference in the change in depression of T1 in the train-of-four group at the larynx and hand during onset of paralysis.

Our findings suggest that video imaging is a useful technique for determining the onset of neuromuscular block at the larynx.

Contractures of malignant hyperthermia muscle: where do halothane and caffeine act?

P. D. SMITH, P. M. HOPKINS, F. R. ELLIS AND P. J. HALSALL
Academic Unit of Anaesthesia, University of Leeds, St James's University Hospital, Leeds

Although the sarcoplasmic reticulum (SR) calcium release channel (ryanodine receptor) is a candidate for a causative defect in malignant hyperthermia (MH), approximately 50% of pedigrees do not show linkage to the relevant gene locus. The crucial role of extracellular calcium and the effects of dihydropyridine agonist and antagonists on the *in vitro* contracture test (IVCT) provide evidence for an effect at the sarcolemma [1]. To examine this further we compared the effects of halothane and caffeine on an intact strip of cut muscle fibres with their effects on the same strip mechanically skinned. Mechanical skinning removes the sarcolemma as an effective barrier and allows free access of solutes to the SR.

Strips of muscle consisting of approximately 50–100 fibres (0.5–1 × 15 mm) were dissected under an inverted microscope. These were mounted horizontally between two clamps in a bathing chamber filled with Krebs solution at room temperature. One clamp was connected via a force transducer to a recorder, the other to a micro-manipulator. The muscle strip was stretched until an increase in tension was first noted and then a further 20 % of this length. The tension changes were recorded while visualizing the reactions to either 2 % halothane or increasing concentrations of caffeine (0.5, 1, 2, 4, 8, 16 and 32 mmol litre^{-1}) in either Krebs solution or a depolarizing solution. The muscle strip was then skinned mechanically by gentle scraping and the tension changes recorded in response to the same drug applied in a solution mimicking intracellular composition. In separate experiments, caffeine or halothane were applied in calcium-free solutions to intact muscle strips. The MH status of each patient was determined using separate IVCTs for caffeine and halothane [2].

The increase in tension of the intact muscle strips correlated with the result of the IVCT for caffeine in Krebs: Spearman correlation coefficient $r = 0.66$, $P = 0.009$, $n = 15$ or in the depolarizing solution $r = 0.69$, $P = < 0.001$, $n = 29$. With halothane in Krebs, the response concurred with the IVCT in 24 of 29 experiments, Cohen's kappa = 0.62 and with halothane in the depolarising solutions in 27 of 33 experiments, Cohen's kappa 0.74. In 12 intact strip preparations from MH susceptible individuals, 2 % halothane in the absence of calcium did not increase tension. In only two of 11 intact strip preparations did caffeine in the absence of calcium cause an increase in tension, and this occurred at four times the caffeine concentration that produced an increase in tension in the presence of calcium. In the mechanically skinned preparations the increase in tension induced by caffeine occurred at lower caffeine concentrations and did not correlate with the IVCT result; Spearman correlation coefficient $r = 0.15$, $P = 0.12$, $n = 15$. The first 33 mechanically skinned preparations exposed to 2 % halothane all produced increases in tension (14 MH susceptible, 19 MH normal).

The IVCT seems to reflect calcium movement across the sarcolemma. We could not distinguish between MH susceptible and normal muscle at the level of the SR.

Hyaluronidase and peribulbar block

G. A. Dempsey*, P. J. Barrett*, and J. Kirby
Aintree Hospitals NHS Trust, Liverpool, and Southport Hospitals NHS Trust

Peribulbar block provides good quality local anaesthesia for intraocular surgery. Hyaluronidase improves the speed of onset and quality of retrobulbar block [1], but its role in peribulbar block has been questioned [2]. We present the preliminary findings of a randomized study investigating the effects of two concentrations of hyaluronidase on peribulbar block.

A total of 198 patients undergoing elective intraocular surgery were allocated randomly to one of three groups. Group 1 ($n = 50$), control) received a peribulbar block using 5 ml of a 1:1 mixture of 0.5 % bupivacaine and 2 % lignocaine. Group 2 ($n = 74$) received this solution supplemented with hyaluronidase 50 iu ml^{-1}. Group 3 ($n = 74$) received the same solution supplemented with hyaluronidase 300 iu ml^{-1}. All blocks were performed by the same investigator using the technique described by Apel and Woodward [3]. Reduction in ocular motility was considered the only reliable sign of successful block and movement of the superior, inferior, medial and lateral recti were scored as follows: normal movement = 2, reduced movement = 1 and akinesia = 0. The block was assessed at 1, 5 and 10-min intervals and a score of 4 or less or reduced movement in all directions was taken to indicate a successful block. A supplementary injection of 2 % lignocaine 3 ml was given if the block was unsatisfactory at 5 min. Further assessment was performed at 5-min intervals. The total volume of local anaesthetic required was recorded. Demographic data were analysed using ANOVA, while ocular motility scores and total volume of local anaesthetic required were compared using chi-square tests.

Table 4 Successful blocks at 5 min. $*P < 0.05$, $***P < 0.001$ compared with control

	Successful block (%)	Unsuccessful block (%)
Control	33 (66)	17 (34)
Hyaluronidase (50 iu)	62 (84)*	12 (16)
Hyaluronidase (300 iu)	67 (91)***	7 (9)

The groups were comparable for age, sex and ASA status. At 1 min, ocular motility scores were significantly lower in group 3 compared with control ($P < 0.05$). The incidence of satisfactory block at 5 min was increased in both groups given hyaluronidase (group 2 $P < 0.05$; group 3 $P < 0.001$) (table 4). There was no statistically significant differences between the number of patients in groups 2 and 3 with satisfactory blocks at 5 min. If a satisfactory block was achieved at 5 min then the 10-min score was omitted. By 10 min, all but two patients had satisfactory blocks. Four patients in the control group had clinical evidence of a sustained increase in intraocular pressure, necessitating, in one instance, cancellation of surgery.

Hyaluronidase 300 iu improves the speed of onset of peribulbar block. Hyaluronidase at both concentrations improves the quality of peribulbar anaesthesia at 5 min after injection. The study will continue in order to determine the optimal concentration of hyaluronidase to use with this technique.

The Deltatrac metabolic monitor for measuring oxygen consumption during orthotopic liver transplantation

T. S. Walsh*, P. Hopton* and A. Lee
Department of Anaesthetics, Scottish Liver Transplant Unit, Royal Infirmary, Edinburgh

Oxygen consumption ($\dot{V}O_2$) increases after reperfusion during orthotopic liver transplantation (OLT). The magnitude of the change may reflect liver oxygen uptake and have useful prognostic value for graft function [1]. The reliability of the reverse Fick method has been questioned recently and this has renewed interest in alternative methods of measuring $\dot{V}O_2$. The Deltatrac metabolic monitor (Datex, Helsinki) calculates $\dot{V}O_2$ by measuring carbon dioxide elimination ($\dot{V}CO_2$) and deriving the respiratory quotient (RQ) from inspired and expired oxygen and carbon dioxide fractions [2]. The assumption is made that a steady state is present and that $\dot{V}CO_2$ results only from metabolic production. $\dot{V}O_2$ is calculated as $\dot{V}CO_2$/RQ. This study was designed to examine when this assumption is valid after reperfusion.

Twenty patients undergoing OLT were studied 30 min before, 30 min after, and 90 min after reperfusion. At each time point an arterial blood gas was taken and 5-min averages calculated from Deltatrac recordings for $\dot{V}O_2I$, $\dot{V}CO_2I$, RQ, and mixed expired

carbon-dioxide fraction (FE_{CO_2}). Pulmonary deadspace ratio was calculated from the Bohr equation. Cardiac index (CI, Baxter Vigilance) was recorded at each study point. Ventilation and FI_{O_2} were not changed during the study period. A total i.v. anaesthetic technique was employed. Statistical analysis was by paired Student's *t*-test.

We attempted to identify and measure factors which influence $\dot{V}CO_2$ other than metabolic production. These include acid-base disturbances, acute changes in lung perfusion and pulmonary deadspace changes. At 30 min after reperfusion an increase in Pa_{CO_2} occurred in association with acute metabolic acidosis as a result of acid washout from the graft and from previously ischaemic tissues. The acute increase in cardiac output and decrease in pulmonary deadspace are consistent with an increase in alveolar perfusion.

Together, these factors will increase $\dot{V}CO_2$ above metabolic production until a new steady state is established. Calculated $\dot{V}O_2$ at this time will be subject to inaccuracy. Between 30 and 90 min no significant changes occurred in Pa_{CO_2}, RQ, V_D/V_T and CI. Standard bicarbonate increased significantly and it is unlikely that continuing acid washout from the graft and splanchnic circulation is contributing to the increase in $\dot{V}CO_2$ at this time. Hydrogen ion concentration remained elevated because ventilation was kept constant throughout the study period. Carbon dioxide stores in the body are large and exist in multiple compartments. It remains possible that $\dot{V}CO_2$ is affected by factors other than metabolic production at 90 min after reperfusion but the resulting error in $\dot{V}O_2$ is likely to be small (table 5).

The measurement of $\dot{V}O_2$ with the Deltatrac metabolic monitor is not straightforward during OLT. Factors other than metabolic production can alter carbon dioxide elimination and should be evaluated when the Deltatrac metabolic monitor is used to estimate $\dot{V}O_2$.

Use of the Bland and Altman statistical method in the anaesthesia literature

I. MALAGON* AND F. J. LAMB*
UMDS Division of Anaesthetics, Guy's Hospital, London and Department of Intensive Care, St George's Hospital, London

Many statistical tests including correlation and regression, are used to compare two methods of clinical measurement. Since 1976, Feinstein [1] reported his concern regarding an author's choice of test. These tests may show an association but do not necessarily support the substitution of one method of measurement for the other. In 1983, Bland and Altman proposed a different way of comparing two methods of clinical measurement [2]. The data should be represented by plotting the difference of two values against the mean. Bias refers to the mean difference while limits of agreement refers to the standard deviation of the mean. This method was further reported in the medical literature in 1986 [3].

We have assessed the use of the Bland and Altman statistical method in the anaesthesia literature. The journals *Anaesthesia, British Journal of Anaesthesia, Canadian Journal of Anaesthesia, Anaesthesia and Intensive Care, Anesthesia & Analgesia* and *Anesthesiology* were chosen. We reviewed by page the original articles from 1 January 1990 to 31 December 1994 and selected the papers reporting a comparison of two or more methods of clinical measurement. Overall, in 1990 six of 26 (23%) original articles used Bland and Altman. The proportion increased to 20 of 30 (66%) during the following year. This figure remained similar from 1992 to 1994 (1992, 10 of 16 (62%), in 1993, 17 of 28 (60%), and 1994, 16 of 26 (61%)).

The type of clinical measurements are associated with the type of statistical test. Thirty one studies compared different methods of measuring cardiac output, and 25 (80%) used Bland and Altman. Fourteen of 23 (60%) articles comparing methods of assessing non-invasive blood pressure measurement used Bland and Altman. A similar proportion, 21 of 33 (63%), was observed for methods measuring blood gases or oxygen saturation. These contrast with the smaller number of papers choosing Bland and Altman to test the relationship between methods of measuring non-invasive end-tidal carbon dioxide (10%) and body temperature (33%). In those original papers where Bland and Altman was not used, data were analysed by regression and/or correlation in 37 articles, *t*-test in 11, ANOVA in four articles and no statistics in five. Despite the success of the Bland and Altman method [3] with over 1500 citations by July 1994, correlation and/or regression are still widely used for the comparison of two methods of clinical measurement in the anaesthesia literature.

Cerebral blood flow and metabolic rate for oxygen after acute brain injury, managed with induced arterial hypertension

L. MASCIA, E. G. MCKEATING, AND P. J. D. ANDREWS
Department of Intensive Care, University of Edinburgh, Western General Hospital, Edinburgh and Department of Intensive Care, University of Bari, Policlinico Hospital Bari, Italy

Advances in the medical treatment of patients with severe brain injury depend upon a better understanding of the pathophysiology including biochemical and blood flow abnormalities that occur after injury. The management of such patients has evolved from an intracranial pressure (ICP) to an arterial pressure (AP)-orientated approach to cerebral perfusion pressure management (CPP) [1]. We report cerebral blood flow (CBF) measurements in

Table 6 Measured variables and calculated variables (median, range)

Variable		Median	Range
CPP	(mm Hg)	72	57–119
CBF	(ml 100 g min^{-1})	90	24.3–441
Pa_{CO_2}	(kPa)	3.91	3.49–4.59
Sj_{O_2}	(%)	67	52–83
$CMRo_2$	(ml oxygen 100 g min^{-1})	4.28	0.45–48.54
MFV	(cm s^{-1})	102	49–160

this patient population with induced arterial hypertension (table 6).

All patients were managed according to a standard procedure that included intubation, ventilation, sedation (alfentanil 0.02 mg kg^{-1} h^{-1} and midazolam 0.07 mg kg^{-1} h^{-1}) and, if necessary, paralysis with atracurium. ICP (Camino transducer), arterial blood pressure, body temperature and jugular venous saturation (Baxter Health Care) were recorded continuously. Therapeutic goals were a CPP of > 70 mm Hg, achieved using noradrenaline infusion (4 μg kg^{-1} h^{-1}); Pa_{CO_2} 4–5 kPa and cerebral venous oxygen saturation of > 50%; manipulated by optimizing CPP and Pa_{CO_2}.

Cerebral blood flow was measured between day 0 and 3 in intensive care, using the nitrous oxide saturation method [2]. Mean blood flow velocity (MFV) in the middle cerebral artery was measured by transcranial Doppler sonography (TCD 2000 EME, Germany).

Seventeen patients were studied on 34 occasions in the intensive care unit after severe brain injury (8 = traumatic head injury; 9 = subarachnoid haemorrhage). All the measures were made when cerebral perfusion pressure (CPP = mean arterial pressure-intracranial pressure) was greater than 57 mm Hg and jugular saturation of oxygen and Pa_{CO_2} within normal limits.

Cerebral blood flow measured in this patient population is greater than previously reported. These results may reflect the effect of inotrope therapy or be due to the limitations of the CBF measurement technique.

Decreased arterial oxygenation during deliberate hypotension: a comparison of trimetaphan camsylate, sodium nitroprusside and glyceryl trinitrate

C. van Oldenbeek* and M. V. Shah

Department of Anaesthesia, The General Infirmary at Leeds and Department of Anaesthesia, Manchester Royal Infirmary

Hypotensive agents may impair pulmonary gas exchange. The effects of trimetaphan camsylate on gas exchange in humans have not yet been fully documented. The aim of this crossover trial was to disclose any differences between the effects of trimetaphan, sodium nitroprusside and glyceryl trinitrate on arterial oxygenation in humans.

Twelve patients were studied, whose lungs were mechanically ventilated following elective coronary artery surgery. Trimetaphan, sodium nitroprusside and glyceryl trinitrate were given to each patient in random succession, aiming for a 20% decrease in mean arterial pressure. Before, during and after infusion of each drug cardiac index (CI), mean pulmonary artery pressure (MPAP), arterial oxygen tension (Pa_{O_2}), mixed venous oxygen saturation (Sv_{O_2}) and shunt fraction (Q_s/Q_t) were determined. Statistical analysis was by two-way analysis of variance.

Trimetaphan decreased cardiac index. All three drugs reduced MPAP, Pa_{O_2} and Sv_{O_2}. Trimetaphan lowered Pa_{O_2} to a lesser extent than did the other two drugs. Both sodium nitroprusside and glyceryl trinitrate increased venous admixture, whereas trimetaphan did not (table 7).

Table 7 Haemodynamic and gas exchange variables before and during a 20% reduction in arterial pressure induced with trimetaphan camsylate (TC), sodium nitroprusside (SNP) and glyceryl trinitrate (GTN). (lsd least significant difference, $P = 0.01$; * = $P < 0.02$ compared with baseline)

	TC	SNP	GTN	lsd
CI (litre min^{-1} m^{-2})				
Baseline	3.73	3.68	3.36	0.47
Hypotension	3.26*	3.80	3.35	
MPAP (mm Hg)				
Baseline	18.0	19.2	18.2	1.7
Hypotension	14.4*	15.3*	14.3*	
Pa_{O_2} (kPa)				
Baseline	16.30	17.42	17.38	1.59
Hypotension	14.87*	12.31*	13.39*	
Sv_{O_2} (%)				
Baseline	74.4	74.3	73.0	2.6
Hypotension	71.3*	71.3*	70.1*	
Q_s/Q_t				
Baseline	0.159	0.145	0.144	0.030
Hypotension	0.158	0.192*	0.184*	

Three possible mechanisms have been postulated to explain a decrease in Pa_{O_2} during deliberate hypotension [1]: first, a reduction in cardiac output and thus mixed venous oxygen content; second, redistribution of blood flow to dependent lung regions as a consequence of pulmonary arterial hypotension; third, inhibition of hypoxic pulmonary vasoconstriction (HPV). In this study trimetaphan decreased Pa_{O_2} by reducing cardiac output. Sodium nitroprusside and glyceryl trinitrate seemed to impair gas exchange by blunting HPV.

Assessment of a model predicted infusion of ketamine used with propofol for total i.v. anaesthesia

C. F. Swinhoe*, C. Gray*, D. G. Mason*, and J. E. Peacock

Departments of Surgical and Anaesthetic Sciences and Automatic Control and Systems Engineering, University of Sheffield

Ketamine may be used in low doses to provide analgesia [1] with little respiratory depression [2] and may therefore be used to augment propofol anaesthesia in spontaneously breathing patients. The aim of this study was to assess the predictive performance and clinical suitability of a ketamine model predicted infusion (MPI) system, used for total i.v. anaesthesia with propofol. This used a computer programmed with ketamine pharmacokinetics [3] and patient weight to control a Graseby 3400 infusion pump. Computer-predicted blood concentrations were compared with concentrations measured by gas-liquid chromatography [2].

Nineteen patients (13 male) of ASA grade I and II, aged 18 to 80 yr within 20% of ideal body weight entered the study. Patients were premedicated with temazepam 20 mg 1 h before surgery. After pre-oxygenation a predicted concentration between 200 and 300 ng ml^{-1} was selected and the infusion started. On reaching the predicted concentration propofol was given to achieve loss of verbal contact. The propofol infusion continued at 10 mg kg^{-1} h^{-1} and was adjusted subsequently as required. A laryngeal mask airway was sited and the patient breathed an air/oxygen mixture to maintain an Sp_{O_2} greater than 95%. After the start of the operation the ketamine concentration was adjusted as clinically indicated. Blood ketamine concentrations were measured before starting the infusion, 5 min later, immediately before the start of the procedure, immediately before an increase in concentration, 3 and 5 min later; immediately before a decrease in concentration, on reaching it and 5 min later; before terminating the infusion, 5 and 10 min later.

The performance error was calculated for each sampling point and the median predictive error (MDPE) and median absolute predictive error (MDAPE) were calculated for each patient and the population as a whole. The model gave effective control of blood ketamine concentrations; MDPE 18.7 (range −12 to 60.7) and MDAPE 22.7 (range 8.9 to 60.7). The technique provided good clinical anaesthesia with mean propofol and ketamine doses of 9.3 and 0.94 mg kg^{-1} h^{-1} respectively. The predicted ketamine concentration ranged from 200 to 500 ng ml^{-1} during maintenance. Six patients had apnoea at induction, but subsequently respiratory depression did not occur, with a mean end-tidal carbon dioxide of 5.9 kPa during maintenance. Mean time (range) to eye opening after terminating the infusions was 13.3 (4–25) min. No patients described unpleasant dreams or hallucinations.

Pharmacokinetics of tenoxicam administered by i.v. or i.v. regional routes

P. Stewart*, P. Taylor*, J. Mason* and G. Hobbs*
University Department of Anaesthesia, Queen's Medical Centre, Nottingham

Tenoxicam is an oxicam non-steroidal anti-inflammatory drug (NSAID) available for i.v. use. Pharmacokinetic data from healthy volunteers and patients with chronic musculoskeletal disorders suggest it has an elimination half-life in excess of 30 h [1]. The kinetics of this drug have not previously been described in patients after operation. There is work suggesting that NSAIDs given into an isolated limb as part of an i.v. regional anaesthetic technique reduce both intraoperative tourniquet pain and postoperative pain [2]. We have investigated the pharmacokinetics of tenoxicam given by both i.v. (IV) and i.v. regional (IVR) routes.

Ten patients undergoing open fixation of an ankle fracture were assigned randomly to receive tenoxicam 20 mg (diluted to a volume of 60 ml with 0.9% saline) either as an i.v. injection after induction of anaesthesia ($n = 5$) or injected into a cannulated vein in the fractured foot after limb exsanguination and inflation of a thigh tourniquet ($n = 5$). Baseline blood samples were taken from a dedicated venous cannula immediately before drug injection (IV group) and during the period of tourniquet inflation (IVR group). Further blood samples were taken at 0.5, 2, 5, 10, 20, 30, 60, 120, 240, 360 min and 24 h after drug injection (IV group) or tourniquet deflation (IVR group). Samples were centrifuged and the plasma stored at −70 °C. Plasma tenoxicam concentrations were measured in duplicate for each sample using high performance liquid chromatography [3]. Pharmacokinetic data were derived from the concentration/time curves using non-linear regression analysis (sum of least squares) and the trapezoidal rule. Concentrations were compared using the Mann–Whitney *U*-test.

There was no systemic leak of tenoxicam (IVR group) during the period of tourniquet inflation. The results for the IV group (but not the IVR group) are described by a tri-exponential decay. Peak plasma concentration in the IVR group was lower and occurred later than in the IV group ($P < 0.05$). After 10 min there was no significant difference in plasma concentration between the two groups. Area under the curve (AUC) analysis showed no difference between the two groups, and estimated the bioavailability in the IVR groups to be 99.5%.

The derived pharmacokinetic variables for the IV group are consistent with previously published data from healthy volunteers. The pharmacokinetic data appear to show that little tenoxicam was retained in the limb when given by an i.v. regional route (table 8).

Table 8 Pharmacokinetic data for the IV and IVR groups (*$P < 0.05$)

	Peak concn (mg $litre^{-1}$)		Time to peak concn (min)		AUC_{24} (mg min $litre^{-1}$)	
	Median	Range	Median	Range	Median	Range
IV group	8.55*	5.6–9.2	0.5	—	2770	2617–3798
IVR group	3.53	2.3–4.4	5.0	0.5–10	3028	1986–4184

Preliminary study of prediction of ICU mortality by artificial neural network

P. C. W. Beatty and D. Young
University of Manchester Department of Anaesthesia, MRI, Manchester Nuffield Department of Anaesthesia, Radcliffe Infirmary, Oxford

Artificial neural networks (ANN) are mathematical non-linear models which can be used for the classification of data or multiple non-linear regression [1]. They learn to estimate unknown output values from known training data and can mix parametric and non-parametric data.

The highest, lowest and initial data in the first 24 h from 800 ICU admissions from the John Radcliffe Hospital, Oxford were used for the study. In addition to the normal data used to calculate APACHE II this data set was treated to give the time between hospital and ICU admission (care delay) and the differences between the raw physiological data values and the mid-points of the APACHE II APS score ranges (difference data). Sex, weight and the time for which the primary illness had been present was also included.

The data set was randomly divided into a training and test data set in the ratio of 7:3. Eight cascade correlation multilayer perceptron classifiers were trained using Neural Works PREDICT software. This software automatically examines the input data to find suitable input data transformations for each of the inputs. It also contains a genetic algorithm that examines the data for the minimum subset of inputs consistent with optimum network performance. Data can be excluded or included under manual control as well as being automatically included or excluded by the genetic algorithm search.

ANN were trained using difference and raw data (ANN A), two nets using raw data only (B, C), difference data only (D), all the available data without any automatic selection of inputs at all (E), a minimum set of inputs repeatedly selected by the genetic algorithm search (F), a more extensive set selected by the software (G) and a network where the chronic health information was forced into the input data set (H). The performance of the networks was then tested using the unseen data. For comparison the APACHE II prediction for the test data was also calculated [2]. The risk value was set to give the same proportion of deaths as in the original data set ($R = 0.3$) (table 9).

The variables selected by the generic algorithm varied considerably between networks, probably indicating that there was insufficient data for optimal training of the networks. The complexity of the networks produced suggests that about 2500 cases would be needed for training and testing of a full ANN

Table 9 Performance of classification methods on unseen test data

ANN	Sensitivity %	Specificity %	Correct class %	False +ve %	False −ve %
A	80.00	81.28	81.14	18.72	16.67
B	72.91	88.00	74.56	27.09	24.12
C	76.74	84.37	83.51	15.63	13.87
D	76.00	76.85	76.75	23.15	20.61
E	65.12	89.97	87.17	10.03	8.90
F	88.00	79.8	80.7	20.2	17.98
G	64.00	84.73	82.46	15.27	13.60
H	84.62	94.98	94.49	5.02	4.78
APACHE II	49.00	94.86	89.14	5.14	4.50

solution [3]. Age, care delay, postoperative status, sex, and Glasgow Coma Score were the variables most often selected by the genetic algorithm. The physiological measurements selected varied but were spread fairly uniformly across the APACHE II set. Chronic Health Status was virtually never selected. When forced uniformly into the training of ANN H it seems to have produced an improvement in the network performance.

Effect of an upper respiratory tract infection on upper airway reactivity

N. Nandwani*, J. H. Raphael and J. A. Langton
University Department of Anaesthesia, Leicester Royal Infirmary, Leicester

Many patients presenting for elective surgery will either be suffering with or recovering from a recent upper respiratory tract infection (URTI). The decision whether or not to anaesthetize such a patient is an enduring clinical dilemma, as there is an increased risk of respiratory complications including laryngospasm [1]. By measuring the threshold concentration of ammonia vapour (NH_3TR) required to elicit reflex glottic closure [2], we aimed to determine whether upper airway reflex sensitivity (UARS) changes during the course of an URTI, how long these changes might persist and whether they are related to the presence of symptoms.

Twelve volunteers were recruited 24–72 h after symptoms of an URTI began. We defined URTI as the presence of nasal and throat symptoms, in addition to general malaise. All volunteers were non-smokers, on no medication and gave no history of asthma or URTI in the previous 3 months. Over the next 8 weeks repeated measures of NH_3TR were made, and symptoms were recorded. Measurements were made on the following days (±24 h) after the commencement of symptoms; 3, 6, 9, 15, 20, 27 and 56.

Eleven subjects (six male), mean age 39.8 (range 30–58) yr, completed the study. One subject was asymptomatic at day 6, 5 at day 9 and 10 at day 15. All were asymptomatic by 20 days, and remained so until the study ended at day 56.

Upper airway reactivity as measured by this technique is increased during an URTI. The changes appear to return to normal by day 15 by which time 10 of the 11 subjects were asymptomatic (fig. 2).

Key words

A fibreoptically guided exchange bougie

D. P. L. Atherton*, E. O'Sullivan and P. Charters
Department of Anaesthesia, Aintree Hospitals, Liverpool

The laryngeal mask airway (LMA) has been advocated for use after difficult and failed intubation [1] and as a guide to visualize the larynx with a fibreoptic laryngoscope (FOL) [2]. We present a new piece of equipment, an exchange bougie (Cook (UK) Ltd). This study evaluates the exchange bougie as a means of performing tracheal intubation. The exchange bougie is 57 cm long with external and internal diameters of 6.5 mm and 4.0 mm respectively. Its side walls are sufficiently rigid so as to prevent it buckling when a tracheal tube is railroaded over it and it is supplied with a 15-mm male connector and so may be used for ventilation. The exchange bougie can be mounted on a FOL and passed into the trachea and guided to the larynx by an LMA. A tracheal tube may then be railroaded over the exchange bougie. A similar technique has been reported in a single patient [3].

Twenty-four adult patients were studied. Anaesthesia was induced with fentanyl, 1.0 $\mu g\ kg^{-1}$ and a sleep dose of propofol; neuromuscular block was produced with atracurium 0.5 $mg\ kg^{-1}$. Anaesthesia was maintained with oxygen and isoflurane. After 3 min an unmodified laryngeal mask airway was inserted, size 3 for women and size 4 for men.

A FOL with an exchange bougie mounted on it was introduced through a tracheal tube connector with a sealed side port. The

FOL was advanced until the larynx was seen. The view of larynx was graded: full, obstructed or not seen. The larynx was then entered and the exchange bougie was advanced into the trachea. The FOL and the LMA were then removed leaving the exchange bougie, over which a tracheal tube was railroaded. The exchange bougie was then removed. The tracheal tube position was then verified fibreoptically. Ease of entering the larynx and of railroading the tracheal tube were scored: easy, difficult or impossible. The period from induction of anaesthesia to completion was timed. Twelve intubations were performed by a consultant experienced in fibreoptic intubation and 12 by a registrar inexperienced in this field.

The average age was 40 yr (SD 15 yr), the average weight was 76 kg (SD 14 kg). All the patients were successfully intubated. There were no significant desaturations (i.e. $Sa_{O_2} < 95\%$).

The view of the larynx was full in 96%. Passage into the larynx and subsequent railroading of a tracheal tube were found to be easy in all patients studied. Mean time from induction of anaesthesia to completion was 357 (SD 78) s.

There was little difference between the results obtained by the experienced fibreoptic intubator compared with the inexperienced investigator, both learning the technique quickly.

The exchange bougie has not been evaluated previously. This technique may permit orotracheal intubation to be performed when direct visualization of the larynx is not possible, either electively or in an emergency. It is a simple technique that may be learnt easily and performed by the inexperienced fibreoptic intubator.

Effect of reduced density gas breathing on oxygenation in ventilated anaesthetized patients

A. Devine*, P. C. W. Beatty, A. J. Mortimer
and I. T. Campbell
University Department of Anaesthesia, University Hospital of South Manchester, Manchester

Anaesthesia produces an increase in alveolar to arterial (A-a) oxygen tension gradient in both ventilated and spontaneously breathing patients. Reducing the breathing gas density using helium in awake volunteers [1] and ventilated animals [2] caused an unexpected increase in (A-a) gradient. We have found the opposite to be the case in anaesthetized spontaneously breathing patients [3] and wished to see if this was also the case when patients were ventilated mechanically.

Ten ASA I-III patients with normal spirometry undergoing elective surgery were selected. Each patient acted as his or her own control, and was anaesthetized using propofol, alfentanil and atracurium. They were intubated and started on propofol, alfentanil and atracurium infusions. The breathing system consisted of a circle circuit with a carbon dioxide absorber and a mixing box on the expiratory limb to measure mixed expired gas. A Pneupac ventilator was connected in place of the reservoir bag. Each patient was chosen randomly to breathe either 40% oxygen in helium or 40% oxygen in nitrogen as the first gas. The fresh gas flow was set to 4 litre min^{-1} for 20 min. Gas flow was then reduced to 300 ml min^{-1} (Capnomac sampling rate 200 ml min^{-1}), the expiratory valve was closed and after a further 5 min, inspired, end-tidal and mixed expired oxygen and carbon dioxide were measured. The second gas mixture was then introduced and the procedure repeated.

There was no difference in minute ventilation or end-tidal carbon dioxide. The A-a oxygen tension gradient was calculated from the alveolar gas equation of Filley, Mackintosh and Wright. Table 10 shows that there was no difference in Pa_{O_2} and no difference in A-a oxygen tension gradient between the groups. However, in the presence of helium, both the arterial carbon dioxide and the a-A carbon dioxide tension gradient were greater than in the presence of nitrogen.

The A-a oxygen tension gradient is not changed by helium, which is not the case when patients are breathing spontaneously [3]. The a-A D_{CO_2} was again higher with helium.

It is postulated that in ventilated patients, reducing breathing gas density limits ventilation distribution or the importance of the effect of diffusion on gas exchange is reduced.

Table 10 Mean partial pressures (SD) in the two groups (kPa)

	Pa_{O_2}	Pa_{CO_2}	$D(A-a)_{O_2}$	$D(a-A)_{CO_2}$
He/O_2	18.03 (5.07)	5.26 (0.67)	17.81 (4.31)	1.69 (0.42)
N_2/O_2	17.39 (6.05)	4.85 (0.58)	16.61 (5.81)	1.17 (0.44)

POSTER PRESENTATIONS

Computer-controlled infusion of propofol for long neurosurgical procedures

T. A. Lim*, C. S. T. Aun and T. Gin*
Department of Anaesthesia and Intensive Care, Chinese University of Hong Kong, Prince of Wales Hospital, Hong Kong

Computer-controlled infusion of propofol for operations of intermediate duration is well documented. This study investigated the performance of such a system during long neurosurgical procedures.

Fifteen patients aged 23–52 yr gave written informed consent for inclusion in the study. Anaesthesia was induced and maintained with a computer-controlled infusion of propofol using variables reported for adult patients [1]. The target concentration was titrated according to clinical requirement. Arterial blood samples were taken at 30–60-min intervals during the infusion, and at 0, 1, 2, 4, 6, 8, 10, 15 and 20 min after stopping the infusion. Propofol concentration was measured using high performance liquid chromatography. The performance of the system was assessed using the median performance error (MDPE), median absolute performance error (MDAPE), wobble and divergence [2] (table 11). Individual concentration–time profiles during recovery were modelled to fit a biexponential equation using the non-linear regression program MKMODEL (Biosoft, Cambridge).

The mean duration of infusion was 7.7 (range 3.7–13.2) h. A total of 284 blood samples were taken for propofol assay. The half-time derived from modelling was shorter than that estimated using the infusion variables in 10 out of 13 patients.

Table 11 Performance measures (25th to 75th percentile)

	During infusion ($n = 15$)	Recovery ($n = 13$)
MDPE (%)	−6.5	−38.7
	(−23–10)	(−52–−24)
MDAPE (%)	19.1	39.0
	(9–31)	(25–52)
Wobble (%)	8.6	5.4
	(2–19)	(2–10)
Divergence (%/h)	0.8	7.7

Propofol pharmacokinetics remain stable during anaesthesia for neurosurgical procedures lasting up to 12 h. However, propofol concentrations during recovery were not predicted accurately.

Is the neuronal dihydropyridine binding site on L-type calcium channels a target for local anaesthetic agents?

T. BROWNE*, K. HIROTA* AND D. G. LAMBERT
University Department of Anaesthesia, Leicester Royal Infirmary, Leicester

As part of a broader programme of research we have recently shown that i.v. anaesthetics interact with neuronal L-type voltage sensitive calcium channels (VSCCs) [1]. Sugiyama and Muteki suggest that local anaesthetics may also interact with L-type VSCCs [2]. In this study we have examined the interaction of procaine, prilocaine, lignocaine, bupivacaine and tetracaine with the 1,4-dihydropyridine (DHP) binding site in rat cerebrocortical membranes.

Rat cortical membranes were prepared in Tris.HCl 50 mmol litre^{-1}, pH 7.4 by homogenization and centrifugation. Binding assays were performed in 1 ml volumes of Tris.HCl 50 mmol litre^{-1}, pH 7.4 for 90 min at room temperature using approximately 200 µg of protein. Non-specific binding was defined in the presence of nifedipine 10^{-5} mol litre^{-1} and bound and free radioactivity were separated by vacuum filtration. The effects of local anaesthetics were determined by displacement of [^{3}H]PN200-110 0.2 nmol litre^{-1}. The concentration of displacer producing 50% displacement was corrected for the competing mass of [^{3}H]PN200-110 using a K_d 59 pM [1] to yield K_{50}.

All local anaesthetics tested displaced [^{3}H]PN200-110 dose-dependently with K_{50} values shown in table 12. There was a significant correlation ($r^2 = 0.895$, $P = 0.015$) between log K_{50} and the log octanol:buffer partition coefficient [3].

These data suggest that, in addition to the classic sodium channel block, local anaesthetic agents also interact with L-type VSCCs. Further studies will examine the role of the phenylalkylamine and benzothiazepine binding site on these channels.

Assessment of vocal cord function using tussometry

R. CARANZA*, N. NANDWANI* AND T. SOMMERVILLE*
University Department of Anaesthesia, Leicester Royal Infirmary, Leicester

Tussometry is a technique for assessing laryngeal function by measuring cough peak flow rate (CPFR) and the time taken to achieve this, the peak velocity time (PVT) [1]. It has been used to assess vocal cord function postoperatively [2]. However, it has been shown that PVT is directly related to CPFR, which in turn bears a direct relation to lung volume during a cough manoeuvre [3]. It has been suggested that interpretation of tussometry is effort independent and our aim was to investigate this.

We studied the expired airflow waveform of 11 healthy volunteers (9 males), mean age 32 (range 22–54) yr. After familiarization with the technique, each subject gave a maximum cough at three different lung volumes; at total lung capacity (TLC), at the end of normal inspiration (VT) and at the end of normal expiration (FRC), and a cough with submaximal effort at TLC.

We found that CPFR and PVT are dependent upon both lung volume and cough effort (table 13). Effect of volume: PVT, $P < 0.05$; CPFR, $P < 0.02$ (Friedman). Effect of effort: PVT, $P < 0.05$; CPFR, $P < 0.05$ (Wilcoxon).

Our results coincide with previous findings that PVT varies directly with CPFR at varying lung volumes [3]. However, there is an increase in PVT and a decrease in CPFR with a reduction in cough effort. In two volunteers, CPFR was greater when submaximal effort was applied.

Key words
Cough. Measurement techniques, tussometry.

Perioperative pharmacokinetics of transdermal fentanyl in young and elderly patients

J. P. THOMPSON, S. BOWER AND D. J. ROWBOTHAM
University Department of Anaesthesia, Leicester and University Department of Anaesthesia, Newcastle

Transdermal fentanyl is indicated for the treatment of pain in patients with malignancy. Although it is not recommended for postoperative pain, these patients may present for surgery and it may be appropriate to continue its use in the perioperative period. Perioperative transdermal fentanyl pharmacokinetics have been described [1] but there are few data comparing young and elderly patients.

Two groups of patients (elderly mean (range) 73.7 (64–82) yr; young 32.7 (25–38) yr) scheduled for lower abdominal surgery

Table 13 Effect of different lung volumes and cough effort on peak velocity time (PVT) and cough peak flow rate (CPFR) (median (range))

	Total lung capacity	End of normal inspiration (VT)	End of normal expiration (FRC)	Submaximal effort (TLC)
CPFR (litre min^{-1})	590 (450–750)	309 (130–570)	275 (150–360)	543 (310–710)
PVT (ms)	38 (13–61)	28 (5–36)	21 (13–31)	52 (32–85)

Table 14 Mean (SD) pharmacokinetic values. No significant differences except pseudo T_{max} (time at the start of the apparent plateau). $**P = 0.01$, Mann–Whitney *U* test. C_{ss} = mean concentration during plateau. ¶ = time after patch removal

	Young	Elderly
T_{max} (h)	24.5 (10.3)	28.1 (12.9)
pseudo T_{max} (h)	9.2 (6.5)	16.3 (6.1)**
C_{max} (ng ml^{-1})	2.0 (0.8)	1.3 (0.7)
C_{ss} (ng ml^{-1})	1.4 (0.6)	1.1 (0.6)
$AUC_{0-\infty}$ (ng h^{-1} ml^{-1})	115 (52)	113 (55)
¶C_{10h} (ng ml^{-1})	0.6 (0.4)	0.7 (0.4)
¶C_{30h} (ng ml^{-1})	0.4 (0.3)	0.5 (0.4)

were studied (20 total). Exclusion criteria were weight < 50 or > 100 kg and significant CNS, respiratory, cardiac, hepatic or renal disease. A fentanyl patch (50 μg h^{-1}, Janssen-Cilag) was applied to the upper anterior chest and temazepam 20 mg given orally 2 h before surgery. Anaesthesia was induced with a sleep dose of thiopentone and maintained with enflurane and nitrous oxide in 33% oxygen. Tracheal intubation was facilitated with atracurium and the lungs ventilated to normocapnia. I.v. morphine 0.2 mg kg^{-1} (young) or 0.1 mg kg^{-1} (elderly) was given. Neuromuscular block was reversed with neostigmine 2.5 mg and atropine 1.2 mg.

Morphine was available via PCA (bolus 1 mg, lock-out time 5 min) during the study. Vital signs and pain scores were recorded regularly and arterial haemoglobin oxygen saturation was measured continuously. The patch was removed 72 h after application.

Blood samples (5 ml) were taken from a venous cannula at 0, 2, 4, 8, 12, 20, 24, 30, 48, 54 and 72 h after patch application and at 0.5, 1, 2, 4, 6, 10, 20, 24 and 30 h after removal. Plasma was separated and stored at −20 °C before measurement of fentanyl concentration by radioimmunoassay (lower limit of detection 2 pg ml^{-1}) [2].

One elderly patient received fentanyl at induction (data not analysed). Patches were removed before the end of the study in three elderly (two respiratory depressions, one postoperative haemorrhage) and two young patients (one nausea, one dislike of blood sampling).

There were no significant differences in standard pharmacokinetic values (table 14). However, in common with many pharmacokinetic studies, the power of these data are low. Significant differences in pseudo T_{max} may reflect reduced skin perfusion in the elderly. The incidence of respiratory depression confirms the view that transdermal fentanyl is not appropriate for postoperative pain management in opioid-naive patients.

Interaction of vecuronium with recombinant human m2 muscarinic receptors

T. M. CEMBALA, B. L. APPADU AND D. G. LAMBERT
University Department of Anaesthesia, Leicester Royal Infirmary, Leicester

We have recently shown that a range of steroidal neuromuscular blocking agents, including vecuronium, interact with the m2 muscarinic receptors present in the rat heart [1]. The interaction of vecuronium was complex yielding two affinity values. However, the major proportion of the binding (80%) occurred with relatively high affinity (K_i 216 nmol $litre^{-1}$). A major criticism of this study relates to the possibility of species differences in the potencies of neuromuscular blocking agents. We have therefore re-evaluated the interaction of vecuronium with recombinant human m2 muscarinic receptors expressed in Chinese hamster ovary (CHOm2) cells.

CHOm2 cells maintained in minimum essential medium at 37 °C in 5% carbon dioxide in air were passaged weekly and refed twice weekly. Muscarinic receptor binding studies were performed in 1 ml volumes of HEPES 20 mmol $litre^{-1}/Mg^{2+}$ 1 mmol $litre^{-1}$ (pH 7.4) buffer containing approximately 150 μg of membranes. In saturation experiments to calculate receptor density (B_{max}) and equilibrium dissociation constant (K_d) cells were incubated with increasing concentrations (0.007–0.867 nmol litre) of a radiolabelled muscarinic antagonist *n*-methyl-scopolamine ([^{3}H]NMS). the affinity of vecuronium and methoctramine (as an m2 selective reference compound) was estimated by displacement of a fixed concentration of NMS (~ 0.4 nmol $litre^{-1}$) with increasing concentrations of vecuronium (10^{-5}–3^{-10} mmol $litre^{-1}$). Tissue was incubated for 1 h at 37 °C and non-specific binding was assessed in the presence of atropine 10 μmol $litre^{-1}$. Bound and free radioactivity were separated by rapid vacuum filtration onto Whatman GF/B filters. B_{max} and K_d were calculated according to Scatchard [2]. The concentration of vecuronium and methoctramine producing 50% displacement of specific binding was corrected for the competing mass of NMS according to Cheng and Prusoff [3] to yield the affinity constant K_i.

The binding of [^{3}H]NMS was dose-dependent and saturable with a B_{max} and K_d of 165 (13) fmol mg^{-1} protein and 0.15 (0.01 nmol $litre^{-1}$ ($n = 5$) respectively. The binding of [^{3}H]NMS was displaced dose-dependently by methoctramine with a K_i of 2.34 (0.17) nmol $litre^{-1}$ ($n = 5$) confirming the expression of a homogeneous population of m2 muscarinic receptors. Vecuronium also produced a dose-dependent displacement of [^{3}H]NMS binding with a K_i of 127 (24) nmol $litre^{-1}$ ($n = 6$).

These data, in cells expressing the recombinant human m2 muscarinic receptor, confirm our previous findings with the rat m2 muscarinic receptor that there is a potent interaction of vecuronium with m2 muscarinic receptors. The K_i value in human appeared approximately twofold more potent than that seen in the rat. Further mechanistic studies are currently under way.

Measurement of desflurane partial pressure in blood

M. A. SMITH*, S. M. SAPSED-BYRNE*, AND G. G. LOCKWOOD
Department of Anaesthesia, Hammersmith Hospital, London

The measurement of the partial pressure of volatile anaesthetics in blood conventionally requires repeated equilibrations of blood with air in the headspace of the vessel containing it [1]. We have previously used head space analysis successfully to measure the partial pressure of isoflurane in blood but met difficulties measuring desflurane with the same technique. We describe a simple modification of the standard method.

In our standard method a 2-ml blood sample is placed in a 5-ml vial and agitated in a waterbath at 37 °C for 15 min, the isoflurane concentration in the vial headspace measured using a gas chromatograph (GC), then the headspace flushed with room air. This equilibration-measurement-flush cycle is repeated three times. A least-squares fit of the four headspace concentrations to an exponential washout allows calculation of both the initial partial pressure and the blood-gas solubility coefficient.

We evaluated this technique using blood in a IL-237 tonometer with 3% desflurane in air as the equilibrating gas. We found a systematic underestimate of the initial partial pressure and an overestimate of the blood gas solubility of desflurane compared with published data. We blamed this on incomplete flushing of the headspace between equilibrations because of trapping of desflurane in bubbles and froth within the vial. The effect of this will be much greater with desflurane than with isoflurane because desflurane is less soluble in blood. We have therefore modified the technique.

After the first equilibration and desflurane measurement, the vial was opened, blood drawn into a syringe from the bottom of the sample and 1 ml was transferred into a new 5 ml vial. For simplicity, only one more headspace equilibration and measurement was made. Let P_0 be the partial pressure of desflurane in the sample when it was first drawn; let P_1 and P_2 be the partial pressures after the first and second equilibrations respectively; let V_v, V_1 and V_2 be the volumes of the vial (4.8 ml), the first blood sample (2 ml) and the sample transferred (1 ml) respectively; let λ be the blood gas coefficient; and let T_{lab} be the laboratory air temperature in K. The GC readings are multiplied by the factor $1.03 \times 210/T_{lab}$ to correct for pressure changes in the vial as a result of humidification and warming of the air. Then equating the amount of desflurane in the vial before and after each equilibration:

$$P_0 V_1 \lambda = P_1 V_1 \lambda + P_1(V_v - V_1)$$

and

$$P_1 V_2 \lambda = P_2 V_2 \lambda + P_2(V_v - V_2)$$

The second equation is solved for λ and this value is used to determine P_0 in the first. P_0 is corrected to dry gas to match the tonometer gas sample. The mean error in the sample measurement ($n = 21$) was −0.2% of the tonometer reading, and the 95% CI for an individual measurement was ±8%. Although the variation in our results is greater than in published work using isoflurane, comparable results for desflurane are not available.

Key words

Anaesthetics volatile, desflurane. Measurement techniques, gas exchange.

CORRESPONDENCE

CSF progesterone and spread of subarachnoid anaesthesia in pregnancy

Sir,—Hirabayashi and colleagues [1] suggested that a sustained (at least 3–4 months) increase in cerebrospinal fluid (CSF) progesterone concentration may be necessary to produce enhanced spread of spinal anaesthesia in pregnant women. We believe that these conclusions are misleading and unsupported by the results.

Maximum cephalad spread of analgesia was quoted as being higher in the second trimester compared with the first, but there were no results of statistical tests that directly compared these two trimesters. Median maximum cephalad spread of analgesia was the same (T4) in the first and second trimesters, and this makes it unlikely, although not impossible, that there was a significant difference between the two groups. The figures do not show all data points, perhaps because overlapping points are not separated, and it was impossible for us to confirm the results.

The CSF progesterone concentration data were also surprising. CSF progesterone concentrations were said to be increased similarly in the early and middle stages of pregnancy. This appeared to form the basis for Hirabayashi and colleagues suggesting that chronic exposure to progesterone increased spread of spinal anaesthesia (assuming that there really is increased spread in the second trimeter compared with the first). However, the results stated that there was ***no significant*** increase in CSF progesterone concentration during early and middle pregnancy compared with the control group. The CSF progesterone concentration data were further complicated by the larger number of patients with undetectable progesterone, even at term gestation. Other studies have detected CSF progesterone concentrations in all patients [2, 3], with mean concentrations at term gestation approximately double those reported by Hirabayashi and colleagues.

Given the wide variation in both the CSF progesterone concentration and the spread of spinal anaesthesia, we are not convinced that a meaningful association can be made between chronic exposure to progesterone and increased spread of analgesia. The study design certainly does not permit one to conclude that progesterone may be a causative factor.

The suggestion that chronic exposure to progesterone may be necessary for increased sensitivity of nerves to local anaesthetics was derived from a series of *in vitro* studies using rabbit vagus nerves [4]. However, the same research group has recently reported that bupivacaine conduction block of B and C fibres in desheathed vagus nerves was similar in pregnant and non-pregnant rabbits [5]. It was concluded that previous data on progesterone and nerve sensitivity to local anaesthetics were a result of increased diffusion of bupivacaine through the nerve sheath rather than a direct action on the nerve itself. Therefore, the effect of progesterone on nerve block after intrathecal administration of local anaesthetics remains uncertain.

Hirabayashi and colleagues quickly dismissed mechanical factors as a possible cause for increased spread of spinal anaesthesia in the second trimester, but did not provide supporting evidence. Anatomically, the gravid uterus is first palpable above the pubic symphysis at 12 weeks' gestation. By 16 weeks' gestation, the uterus extends above the sacral promontory where the inferior vena cava usually bifurcates [6]. Caval compression may occur in early pregnancy. When pregnant women of 13–16 weeks' gestation were placed supine, direct femoral venous pressure measurements increased by 50% [7]. It is thus possible that a progressive increase in caval compression throughout pregnancy may contribute to a progressive increase in the spread of spinal anaesthesia.

Although not specifically stated in the article, we wonder if data from some of the patients in this study have been reported previously [8]. In that article, it was also concluded that maximum cephalad spread of analgesia was higher in the second trimester compared with the first. Again, there were no statistics provided that directly compared the two trimesters.

By arguing that spread of sensory block in the second trimester is greater than that in the first trimester but similar to that at term, the authors have implied in both reports that there is a cut-off point in the second trimester where spread of sensory block increases. Given the progressive nature of pregnancy and artificial division of gestation into trimesters, it may be just as likely that there is a gradual increase in spread of sensory block from the non-pregnant state to term gestation, whatever the cause(s).

We also suggest that there may be bias in the conclusion that CSF progesterone concentrations were greater in twin pregnancies compared with singleton pregnancies in the third trimester. Figure 1 shows that in the third trimester group (25–36 weeks), at least four of the singleton pregnancies were between 25 and 27 weeks, while none of the twin pregnancies was less than 32 weeks. There is an inconsistency between table 1, which lists the smallest weight in the second trimester group as 50 kg, and table 2, where the corresponding minimum weight is 40 kg.

Sir,—In our study, we found a small, non-significant increase in CSF progesterone concentration in the first trimester and second trimester groups. In addition, we found higher cephalad spread of analgesia in the second trimester group compared with the non-pregnant group. Cephalad spread of analgesia in the first trimester group was similar to that of the non-pregnant group. From this we concluded that not only a minimum concentration of progesterone in CSF but also a particular duration of exposure to elevated CSF progesterone concentrations may be necessary for enhancement of spread of spinal anaesthesia. I studied the report of Lambert and colleagues [1] and understood that the effect of pregnancy on neural block observed in their earlier studies [2, 3] may be caused by increased diffusion of bupivacaine through the nerve sheath and not a direct effect on the nerve itself. Both CSF progesterone concentration and spread of spinal anaesthesia show a wide variation in clinical practice. Consequently, I also understand that further studies are needed to draw final conclusions on the direct involvement of progesterone with pregnancy-induced enhancement of spinal anaesthesia.

Because unfortunately we did not measure plasma progesterone concentration simultaneously in our study, we cannot determine the reason why there are some disparities in CSF progesterone concentration between previously reported studies and ours. I suggest that racial differences might contribute to the disparities.

By 20 weeks of pregnancy the uterus is spheroid, and thereafter becomes more and more elongated as the conceptus is converted from spheroid to cylindrical form [4]. At 16 weeks, the fundus of the uterus rises to approximately half of the distance between the symphysis and the umbilicus, and it is at the umbilicus by 20 weeks [5]. The spheroidal uterus may occupy a considerable space in the pelvic cavity and may increase femoral venous pressure. However, it remains uncertain if this increase in femoral venous pressure is accompanied by engorgement of the extradural venous plexus. Many patients with gynaecological tumours have an increased femoral venous pressure comparable in magnitude with that seen in the latter months of pregnancy [6]. However, to our knowledge, there are no studies which demonstrate that such patients usually show higher spread of spinal anaesthesia compared with patients without gynaecological tumours. I suggest that the inferior vena cava, which is formed on the right side of the 5th lumbar vertebra by the junction of the two common iliac veins [7, 8], may not be compressed by the spheroidal uterus. Nevertheless, because there are no studies which have determined when the enlarged pregnant uterus begins to compress the inferior vena cava and engorge the extradural venous plexus [9], further studies focusing on this issue should be performed.

We reported previously on the spread of subarachnoid hyperbaric amethocaine in pregnant women [10]. In that report, we collected data on the spread of sensory block from 90 patients. We anaesthetized these patients with amethocaine 8 mg, but did not collect any CSF. The patients in our previous study differed from the 134 patients in the present study in which 1 ml of CSF was withdrawn just before administration of amethocaine 8 mg. Both the methodology and patients examined in these two studies were different.

I agree with the suggestion that artificial division of pregnancy into trimesters is not possible for evaluation of pregnancy-induced enhancement of spread of spinal anaesthesia which may increase gradually. However, I believe that this division of pregnancy into trimesters, which is standard practice in prenatal care, provides useful information in clinical management of spinal anaesthesia. Pregnancy during the first trimester does not affect spread of spinal anaesthesia, while pregnancy during the second trimester until term enhances it. What is required is to determine when enhancement begins to develop, especially in the second trimester of pregnancy.

We had compared CSF progesterone concentrations in 40 twin pregnancies (median 36 (range 12–38) weeks of pregnancy) with those in 81 singleton pregnancies (37 (8–41) weeks of pregnancy), when we analysed the data in the present study. The results confirmed that CSF progesterone concentrations were greater in twin pregnancies than in singleton pregnancies (mean 1.51 (SD 1.33) ng ml^{-1} *vs* 0.73 (0.83) ng ml^{-1}; $P = 0.001$). Finally, table 1 in our article contains an error. The smallest weight in the second trimester group was 40 kg (not 50 kg). This typographic error has not affected the statistical analyses and we apologize for this mistake.

Sevoflurane

Sir,—I read with interest the recent review article on sevoflurane [1]. There are, however, two points that were inadequately considered.

The section on renal toxicity was largely limited to the effects of increased serum fluoride concentrations; the potential for renal toxicity caused by renal tubular damage after production of compound A was questioned [1]. The authors failed to highlight that the clinical studies to date, although without reports of nephrotoxicity, have largely examined indices of glomerular function [2, 3]. The functional reserve of the kidney prevents renal toxicity being detected, except in circumstances of severe injury. Studies that have attempted to assess tubular damage have used relatively high fresh gas flows, thereby limiting production of compound A [4]. This also reflects the difficulty in accepting the large clinical experience gained with sevoflurane in Japan, because of the commonly used high fresh gas flows. The safety of sevoflurane in low-flow anaesthesia remains to be established.

In the discussion regarding the renal toxicity of compound A, the authors mentioned a conflict of interest in a previous study [5] and the effect this may have on objectivity [6]. The source of research funding, and the possible effect on bias and integrity, are important issues that should always be declared. In contrast, the authors failed to acknowledge their own previous involvement with Abbott Laboratories [7]. This clearly represents a similar conflict of interest to the one they highlighted. Omission of this fact from the article represents a considerable oversight that must be addressed. As Dr Saidman stated "the overriding opinion is that all relevant financial interests and potential conflicts be disclosed, which at a minimum allows the audience, be it the readership of a journal or those attending a lecture, to judge themselves whether the data being described are accurate, and that the conclusions and recommendations are fairly stated" [6].

parison with propofol. *Anesthesia and Analgesia* 1995; **81**: 823–828.

Sir,—Thank you for allowing us to respond to Dr Daniel. Our section on renal toxicity was primarily directed towards elevated serum fluoride concentrations because human nephrotoxicity has occurred previously with methoxyflurane. Until relatively recently, toxicity was believed to be an inevitable consequence of exceeding a "threshold" serum fluoride concentration. As concentrations in excess of 50 μmol litre^{-1} are not infrequently produced by exposure to clinically relevant concentrations of sevoflurane, it was necessary to examine the evidence for fluoride-related nephrotoxicity with sevoflurane. It was partly the lack of such toxicity which has led to an increased understanding of the relationship between fluoride-producing anaesthetics and renal damage.

In contrast, it is not known if compound A is nephrotoxic to *humans* or, if it is, by what mechanism or at what concentrations. In the rat, compound A *is* nephrotoxic. The LD_{50} is approximately 1000 ppm, although histological signs of tubular damage are seen in rats exposed to concentrations of 50 ppm or more of compound A. It is not yet clear what is the natural history of these lesions in rats. Of greater importance, it is by no means certain that compound A is as toxic to humans as it is to rats. Recent evidence from Kharasch's group [1] suggests that compound A has to undergo further metabolism to produce nephrotoxicity. The pathway by which this occurs is approximately 10 times more active in rodents compared with humans, suggesting that compound A may indeed be substantially less harmful to humans [1]. This is supported by the absence to date of *any* signs of renal dysfunction (tubular or glomerular) in humans exposed to sevoflurane under a wide range of clinical conditions. A recent Japanese study showed no evidence of renal or hepatic toxicity after 13 MAC-h of anaesthesia in 50 patients exposed to sevoflurane at a total flow rate of 1 litre min^{-1} [2]. Rather than "limiting compound A production", this regimen produced a mean level of 24.6 ppm (range 13.6–41.3 ppm). Nevertheless, postoperative indices of hepatic and renal function did not differ significantly from a control group who received a comparable isoflurane anaesthetic [2]. Although it is true that much of the Japanese *clinical* experience involves moderately high flows, the routine use of sevoflurane since the early 1990s in Japan has encompassed a far broader range of conditions and pre-existing pathologies than would ever be allowed within the constraints of a research project. Despite this, no pattern of renal damage has emerged. The author may be correct when he stated that "the functional reserve of the kidney prevents renal toxicity being detected except in circumstances of severe injury". However, the same mechanism also limits the clinical significance of any such minor toxicity [3]. Finally, the Committee on Safety of Medicines has reviewed published data on sevoflurane and data on file with Abbott (which was not available to the authors of this review) and concluded that there is no evidence to support the avoidance of sevoflurane in low-flow anaesthesia.

With regard to conflict of interest, the authors have previously (in common with many other researchers) received financial support from the pharmaceutical industry to conduct clinical studies. Two of our previous studies with sevoflurane received such support [4, 5], which was openly declared when they were published. Many of the articles by other authors which we reviewed will also have received commercial support. However, the authors are not employed (partly or wholly) by Abbott, they did not receive any financial support from Abbott in association with the production of this review article, and the article was not submitted to Abbott for review before publication. In addition, some of the authors have also previously received financial support from ICI-Zeneca (the makers of propofol), Ohmeda and Pharmacia (the manufacturers and distributors of desflurane) for studies with products which could be considered commercial "rivals" to sevoflurane. For these reasons, we did not mention our previous "involvement" with (any) pharmaceutical company. In contrast, the conflict of interest referred to in our review concerned work relating to sevoflurane by an individual who is a paid consultant to Ohmeda, the manufacturers of a rival product. The authors accept that in an ideal world, all research would be totally independent of drug company finances. However, is there not a difference between industry support of research and a regular income for advising a pharmaceutical company on marketing and promotional matters? Perhaps the readership of the *British Journal of Anaesthesia* would like to judge this issue for themselves.

Removal of extradural catheters

Sir,—Two previous communications [1, 2] have commented upon removal of extradural catheters. My experience supports the view put forward by Morris [2]. In two cases of ankylosing spondylitis who had undergone total hip replacement the junior resident was unable to remove the extradural catheter on the fourth post-operative day; in both, the extradural catheter had been inserted in the left lateral position under general anaesthesia. The lumbar spine in both patients was partially fused and the extradural placement was technically difficult. I was also unable to remove the catheter in the flexed sitting position, but on turning the patient into the left lateral position with flexion, the catheters were removed without any problems.

In the postoperative period, extradural catheters are usually removed in the flexed sitting position because of patient comfort. I suggest that in patients with technically difficult extradural catheter placement the catheter should be removed in the same position as that used for insertion and undue force should not be applied. I further suggest that the nurses and residents should be made aware of this simple manoeuvre, and the position in which a catheter has been inserted should be written on the anaesthesia records.

Optimal intracuff pressures with the laryngeal mask

Sir,—We read with interest the article by Morris and Marjot demonstrating that laryngeal mask airway (LMA) cuff pressures can be reduced to 22 mm Hg without significantly affecting tidal ventilation in spontaneously breathing anaesthetized patients [1]. While agreeing that reducing intracuff pressure may minimize pharyngeal morbidity, we suggest that perioperative cuff deflation to such low pressures may be potentially hazardous.

A major function of the LMA cuff during spontaneous breathing is to protect the larynx from oropharyngeal saliva. To perform this function an oropharyngeal leak pressure of up to 10 cm H_2O may be required (the approximate pressure of fluid at the posterior pharyngeal wall if the oral cavity is flooded). An intracuff pressure of 22 mm Hg may or may not be sufficient to ensure an adequate seal to prevent contamination of the larynx with oropharyngeal secretions depending on the factors outlined above. We would therefore suggest that in patients undergoing spontaneous ventilation a leak pressure of greater than 10 cm H_2O is a more useful guide to airway safety than intracuff pressure alone. Other factors, such as avoidance of lignocaine gel for lubrication, choice of correct size of LMA and ensuring that tension in the pilot balloon does not increase during nitrous oxide anaesthesia may help minimize the risks of pharyngeal morbidity.

The authors infer that pharyngeal mucosal blood flow may be significantly impaired at commonly used cuff pressures. This concept was based on a study by Marjot where mucosal pressures were calculated, but not measured directly [2]. Hamakawa, Nakamura and Kawasaki directly measured the pressure on the middle part of the outside of the LMA and showed that extracuff pressure is approximately 25 mm Hg and does not increase during oxygen–nitrous oxide anaesthesia, despite increases in intracuff pressure [3]. Although there are obvious limitations to measuring pressure at one arbitrary point, this study may help to explain why pharyngeal morbidity is uncommon. It also confirms that the relationship between intracuff and pharyngeal mucosal pressure is non-linear making guidelines based on intracuff pressures alone less useful.

It is important to distinguish between pressure in the cuff, pressure exerted by the cuff on the mucosa and pressure in the airway at which leaks occur. Unfortunately because of the nature of the anatomy surrounding the mask and the low probability that the mask is exactly the right size for any given patient, there can be no fixed relationship between these three variables. It is therefore logical to determine an intracuff pressure which provides an effective seal empirically, a "just seal" pressure. This value is higher if the mask is small relative to the anatomical space available and lower if the mask is large relative to the available space. For this reason it is sensible to choose as large a size of mask as possible in order to ensure the "just seal" pressure is as low as possible. The smaller the mark relative to the patient, the weaker the relationship between intracuff pressure and average pressure on the mucosa, as the elastic material of the cuff is being stretched relatively more than the tissues surrounding it. On the other hand, because the cuff surface becomes more rigid with increasing intracuff pressure, local high pressure points may develop if excessive stretching of a small mask is resorted to as a means of achieving a seal in a large patient. The inventor suggests that to determine correct mask size a good rule of thumb is to use the largest size which is not displaced out of the pharynx after insertion when the cuff is inflated to a pressure of 60 cm H_2O.

Finally, a new recommendation is to appear in the forthcoming updated LMA instruction manual stating that smoothest recovery is likely to be obtained by reducing intracuff pressure to the minimum required to maintain an effective seal. This must be done with care to avoid accidental laryngeal contamination and should be carried out by the anaesthetist rather than delegated to the recovery staff. Cuff overinflation may cause premature rejection of the LMA or provocation of incomplete and therefore ineffective reflex responses. This may promote laryngeal spasm or regurgitation. Full deflation of the cuff should only occur synchronously with removal of the LMA to avoid secretions entering the larynx and provoking laryngeal spasm. Alternatively, the LMA may be removed with the cuff still moderately inflated to aid more complete removal of salivary secretions.

Sir,—Thank you for the opportunity to reply to Drs Brimacombe, Berry and Brain.

The excessively high intracuff pressures of the laryngeal mask *in situ* have been reported by various independent workers [1–3]. There are two crucial questions raised by this finding.

First, is a significant proportion of this pressure arising as a result of pressure on the adjacent pharyngeal mucosa? There is evidence to suggest that this is the case [2, 3], although no one as yet has implanted a pressure transducer into the pharyngeal mucosa. We were unable to trace the referenced work by Hamakawa, Nakamura and Kawasaki from the citation given. Our study was designed to determine if the manoeuvre of reducing intracuff volume and pressure during anaesthesia, which have been advocated by these authors and others [1, 4–6], was feasible in practice. To this end, we reduced intracuff pressure to the unequivocally "safe" pressure of 22 mm Hg (that of an estimated mucosal capillary perfusion pressure), and studied its effect on the primary function of the LMA, namely the unobstructed conveyancing of tidal ventilation from the anaesthetic breathing system to the patient's lungs. Any secondary function of laryngeal protection from oropharyngeal secretions was not investigated (although there was no evidence of this manifesting as laryngospasm, coughing, etc). We agree that unless intracuff pressure is reduced to a safe level, then monitoring is meaningless, as it is impossible to distinguish that proportion resulting from pressure on the mucosa and that of stretching the cuff. Yet, intracuff pressure monitoring is still recommended by the manufacturers and others [1, 7, 8]. The advice to deflate the cuff to a 10 cm H_2O "leak pressure" and the feeling of the "tension of the pilot balloon" would seem to be crude and unsubstantiated gauges of intracuff and therefore mucosal pressures. However, these may be the simplest methods of ensuring cuff volumes are kept to a minimum in practice.

The second question is whether pressure on the pharyngeal mucosa by the LMA cuff causes problems. Are we looking for a cure to a problem that does not exist? The LMA has rightly been embraced into anaesthetic practice throughout the world. The paucity in the international literature of morbidity resulting from the LMA cuff would indicate that the risks are very small. Perhaps it is now time to acknowledge this and dispense with the recommendation of intracuff monitoring, then the LMA could rest (or wedge) in peace.

Prevention of cardiovascular response to tracheal intubation

Sir,—We were interested to read the recently published article on the effects of nicardipine, diltiazem and verapamil in controlling the cardiovascular responses to tracheal intubation by Mikawa and colleagues [1]. We would like to offer some comments.

The authors stated that anaesthesia was induced in a rapid-sequence manner by administering thiopentone and vecuronium, and ventilating the lungs with 1% isoflurane and 50% nitrous oxide in oxygen, and laryngoscopy was carried out 2 min after administration of thiopentone–vecuronium. This is not the correct use of an accepted terminology. The accepted meaning of rapid-sequence induction of anaesthesia is a sequence which allows rapid intubation of the trachea without manual ventilation of the lungs and with cricoid pressure applied to prevent passive regurgitation and aspiration of gastric contents.

Verapamil is effective in attenuating the pressor response but does not control the tachycardia after laryngoscopy and intubation [2, 3]. In this study, heart rate was increased from a mean of 80 to 100 beat min^{-1} or more after administration of verapamil before laryngoscopy and intubation. With these values, it is difficult to conclude, as they did, that verapamil successfully attenuated the increase in heart rate after intubation. In their previous study using a similar anaesthetic technique, they could not demonstrate the role of verapamil in preventing the tachycardic response [2]. In this study, it may have been possible to demonstrate attenuation of tachycardia if they had omitted atropine as premedication.

With regard to measurements of plasma concentrations of adrenaline and noradrenaline, it has been shown that N-type calcium channels are responsible for release of neurotransmitters, and so-called classic calcium channel antagonists such as nicardipine, verapamil, diltiazem and others do not have much interaction with these channels [4]. On theoretical grounds it would be expected that these calcium channel blockers would have no effect on plasma concentrations of catecholamines after laryngoscopy and intubation.

Among the different methods used for attenuating undesirable cardiovascular responses to tracheal intubation, short-acting opioids appear to have a reliable and constant effect but they may contribute to postoperative respiratory depression. Lignocaine is the drug used most often, but its efficacy has been questioned in recent studies [5, 6]. Nebulized bupivacaine is only partially effective in blunting the haemodynamic response to tracheal intubation [7]. Beta blockers prevent tachycardia more than the pressor response [8] and because of their depressant effect on the myocardium, their role still remains to be defined, especially in patients with cardiac disease. A combination of esmolol and alfentanil has been shown to reliably suppress the response to laryngoscopy and intubation [9]. Clonidine and calcium channel blockers seem to be less effective in preventing haemodynamic alterations [10]. The risk of hypotension from calcium channel blockers such as nicardipine and verapamil when used with inhalation agents for maintenance of anaesthesia should be constantly borne in mind. Therefore, in clinical practice it is more appropriate to use a sufficient dose of an ultra-short-acting drug with a rapid onset to attenuate both hypertension and tachycardia. This should neither potentiate the depressant effect of anaesthetic agents used for maintenance of anaesthesia nor potentiate neuromuscular block.

Analgesia: dose-effect or pre-emptive effect?

Sir,—We were interested to read the recently published double-blind study on the influence of dose and timing of administration of morphine on postoperative pain and analgesic requirements by Mansfield, James and Kinsella [1] and would like to offer some comments.

In this study patients undergoing abdominal hysterectomy were allocated randomly to receive one of three different analgesic regimens: morphine 0.3 mg kg^{-1} before the start of surgery (pre-high), morphine 0.15 mg kg^{-1} before surgery (pre-low) and morphine 0.15 mg kg^{-1} at the start of abdominal closure (post-low). The dose of i.v. morphine given in the recovery room, total 24-h morphine PCAS requirements and total dose of morphine in the perioperative period, including that given in theatre, were recorded. Statistical analysis revealed reduced 24 h use of morphine in the pre-high group compared with the pre-low and post-low groups. When total perioperative morphine consumption was analysed, there was a significant difference between the pre-high and post-low groups only. On the basis of these analyses the study reported evidence of pre-emptive analgesia.

We are concerned that patients given morphine 0.15 mg kg^{-1} on abdominal closure apparently received no intraoperative analgesic supplements other than 66% nitrous oxide. Could the authors comment as to how adequate analgesia was ensured in the peroperative period in order to satisfy ethical considerations in the post-low-dose group?

Is it possible the results of this study indicated that a large dose of morphine provided better analgesia than a small dose of morphine, rather than providing evidence of pre-emptive analgesia? It is unclear if the analysis of 24-h postoperative morphine dose included total PCAS requirements in the first 24 h in addition to recovery room analgesic requirements, as no specific information was given on the dose of morphine administered immediately after operation in the recovery room. If 24-h morphine requirements included both recovery room morphine supplements and 24-h PCAS requirements, it is possible that administration of morphine in the recovery room was solely responsible for the significant differences. In theory, pre-emptive analgesia should reduce both immediate postoperative requirements and subsequent PCAS needs. However, a larger dose of morphine without a pre-emptive effect would still reduce immediate postoperative analgesic requirements, although it would not influence later PCAS needs. In order to correctly interpret the statistical analysis of this study, a comparison of immediate analgesic requirements in the recovery room and subsequent 24-h PCAS requirements would be helpful.

The total dose of morphine given in the perioperative period did not differ between the pre-high (63 mg) and pre-low (65 mg) groups. The 24-h postoperative and total postoperative requirements did not differ between the pre-low and post-low groups, and therefore it seems questionable to conclude that pre-emptive morphine reduced postoperative analgesic requirements. We believe the results of this study are consistent with a different interpretation, that is a higher dose of morphine gives better postoperative analgesia than a low dose of morphine. If this is the case then the findings of this study are consistent with those of Collis and colleagues [2] where no significant difference was found in postoperative analgesic requirements in patients who received morphine 10 or 20 mg before operation.

Relative lack of pre-emptive effect of opioids could probably be explained in terms of "*fos* expression" which is a useful marker of the effect of peripheral noxious stimuli on postsynaptic spinal cord neurones. *Fos* expression is not completely suppressed even with a very high dose of systemic morphine, given before onset of nociceptive stimuli, indicating that substantial nociceptive traffic can still occur [3]. There has been a concern that pre-emptive administration of opioids apparently increases pain perception in the late postoperative period [4, 5].

Various randomized controlled trials with NSAID, local anaesthetic block, opioids, including morphine, administered before operation have failed to show any pre-emptive effect on postoperative analgesia [6]. Even multimodal analgesia before surgery did not reduce post-thoracotomy pain or analgesic requirements [7]. However, an NMDA antagonist administered before and after injury has been shown to improve analgesic effect [8] and future clinical trials of pre-emptive analgesia using an NMDA antagonist and morphine would be worthwhile.

Sir,—Thank you for the opportunity to respond to the points raised by Drs Mallick and Dearden. They are correct in stating that patients in the post group (morphine 0.15 mg kg^{-1} on peritoneal closure) received no analgesia other than nitrous oxide until near the end of operation. All patients did, however, receive morphine either before or during surgery, well before awakening after general anaesthesia. In addition, the pattern of analgesic consumption and pain scores do not support the hypothesis that the post group suffered significantly more pain than the two other groups. As this method has been used by other workers, including Richmond and colleagues (reference [4] quoted by Mallick and Dearden), we do not believe there is any ethical dilemma relating to our methodology.

Drs Mallick and Dearden ask if it is possible that our study "indicated that a large dose of morphine provided better analgesia than a small dose, rather than evidence of pre-emptive analgesia". First, we did not demonstrate better analgesia in the pre-high group (although pain scores were consistently lower in this group, the difference between groups was not statistically significant). Second, we were careful not to conclude a pre-emptive analgesic effect from our results. We did conclude that "a large dose of morphine administered on induction of anaesthesia significantly reduced postoperative morphine requirements from a PCA machine compared with a smaller dose given on induction of anaesthesia or at the time of abdominal closure". While it is possible that this is indeed a pre-emptive analgesic effect of a large dose of morphine, we have not tested this hypothesis in our study.

Table 1 shows the amount of morphine administered by us in the recovery ward and PCA morphine use by the patient, from the end of surgery until 24 h after operation.

Table 1 Morphine consumption in the recovery room and PCA morphine use, from the end of surgery until 24 h after operation (median (interquartile range))

	Group		
	Post ($n = 18$)	Pre-low ($n = 22$)	Pre-high ($n = 20$)
Morphine in recovery (mg)	3.5 (0–17.5)	3.0 (0–7.5)	0.0 (0–5.0)
24-h PCA morphine (mg)	61 (51–79)	54 (45–65)	40 (30–49)

While there appears to have been less morphine administered in recovery in the pre-high group compared with the post group, this was not statistically significant ($P = 0.45$, Kruskal–Wallis). As found in the original data analysis, there was a significant difference in the amount of morphine used by patients (PCA) in the pre-high group compared with the post group ($P = 0.0002$) and the pre-low group ($P = 0.0015$, Kruskal–Wallis) but there was no difference between the pre-low and post groups. The suggestion by Mallick and Dearden that the difference in postoperative morphine consumption was caused primarily by an effect in the recovery room is not, therefore, supported.

Finally, we agree with the hypothesis that NMDA antagonists may have a useful role in postoperative pain relief, although this was not tested in our study. Whether they will prove to have a pre-emptive effect remains speculative. It seems unlikely that any single group of analgesic agents will ever be able to abolish pain completely, and that multimodal analgesic strategies are required to optimize postoperative pain relief.

Convective warming after CABG

Sir,—I read the article of Harrison and Ponte on convective warming [1] with great interest. Have the authors considered the effect of propofol on thermoregulation? It was administered to all patients at a rate of 50–200 mg h^{-1}. Propofol is a well known vasodilator and may have caused vasodilatation in addition to that caused by glyceryl trinitrate. Propofol is also known to attenuate adrenaline and noradrenaline release which would alter the rate of thermogenesis [2]. Was there any significant difference between the dose of propofol administered in each group?

The authors administered glyceryl trinitrate at a rate of at least 15 mg h^{-1} to both control and study patients. As the effect of the Bair Hugger is to cause further vasodilatation, did the authors find that less glyceryl trinitrate was subsequently required in this group compared with the control group, and if so, could this have influenced their results?

The authors dismissed the possibility that large doses of glyceryl trinitrate used in the study accelerated cutaneous heat loss from the control group because of rewarming "at a rate close to that usually observed in the absence of glyceryl trinitrate". It would have been interesting to know how the rate of rewarming in the control group compared with "that usually observed". It appears that peripheral temperatures in the control group were significantly colder during the first 2 h after operation compared with the Bair Hugger group. As heat from the peripheral compartment does not flow up a gradient to the core, it would appear that peripheral cooling could only be caused by loss of heat across the skin to the environment.

The peripheral temperature sites of toe and fingertip may be inaccurate in patients with severe peripheral vascular disease. Were these patients excluded from the study?

2. Biddle NL, Gelb AW, Hamilton JT. Propofol differentially attenuates the responses to exogenous and endogenous norepinephrine in the isolated rat femoral artery *in vitro*. *Anesthesia and Analgesia* 1995; **80**: 793–799.

Sir,—Our purpose was not to study thermoregulation. For example, in the methods section we stated clearly that thermoregulatory shivering was deliberately abolished; similarly, the doses of glyceryl trinitrate used in both groups were aimed at overcoming physiological mechanisms (thermoregulatory or not) of cutaneous vasoconstriction. The aim of the study was merely to find out if forced warm air could increase the rate of rise of rectal and nasopharyngeal temperature having deliberately minimized thermoregulatory mechanisms, as stated in the discussion section.

The rate of rewarming "usually observed" refers to that observed in most other patients subjected to similar operations in our department, but not included in the study, which is similar to that quoted in references [6, 7 and 16] of our paper. No patient with diabetes or evidence of peripheral vascular disease was included in the study. Apart from the differences between groups described in the results section, there were no other differences in other variables, such as amount of glyceryl trinitrate or propofol infused.

Adequate general anaesthesia—what are we trying to achieve?

Sir,—Further to the article by Sun, Shyu and Shieh [1] and the accompanying editorial [2], we wish to bring your attention to some relevant findings of studies which were carried out by us in 1995.

We refer in particular to an article on inhibition of nociception-induced spinal sensitization by anaesthetic agents [3]. In this study we sought to determine: (1) if volatile agents reliably block spinal sensitization, (2) if nitrous oxide alone blocks spinal sensitization, (3) if nitrous oxide interferes with the ability of volatile anaesthetics to block sensitization, and (4) if equipotent concentrations of commonly used volatile anaesthetics have different abilities to block sensitization. We found that rats that received halothane, enflurane, isoflurane, desflurane or nitrous oxide during phase 1 of the formalin test demonstrated a significant decrease in phase 2 activity compared with controls, that is suppressed spinal sensitization to pain, with desflurane causing the most suppression. Those rats that received a combination of nitrous oxide and halothane exhibited no difference, that is no suppression was demonstrated.

There is now increasing evidence that volatile anaesthetic agents exert their effect at the spinal cord level [4–7] and this may explain their possible role in pre-emptive suppression of spinal sensitization. There are also many studies which suggest that inhalation anaesthetic agents may suppress nociception in the spinal cord by modifying the activity of NMDA receptors in dorsal horn neurones [8, 9]. While the mechanism by which inhibition of transmission of noxious stimulation by inhalation anaesthetic agents is achieved is still speculative, it has been well documented that they enhance $GABA_A$ mediated sensory inhibition [10–13] and it has been suggested that inhalation anaesthetics may produce suppression of spinal cord sensitization through $GABA_A$ mediated agonism [14].

Some of the analgesic action of nitrous oxide has also been attributed to depressant action on dorsal horn neurones in the spinal cord, perhaps via activation of a supraspinal descending inhibition system. Interestingly, nitrous oxide has been shown to reverse EEG burst suppression provided by isoflurane [15, 16] and desflurane [17], suggesting that it opposes the effect of volatile anaesthetics on the central nervous system. It has also been demonstrated that nitrous oxide has antagonist effects on the MAC of volatile agents [18]. Taken together, these studies indicate that nitrous oxide may antagonize the depressant effects of volatile agents on the central nervous system and this may explain its apparent antagonism of suppression of spinal sensitization by volatile agents in the rat formalin test.

Sir,—We thank Drs O'Connor and Abram for their interest in our article [1].

In their letter they highlight the results of their study in which they tested the efficacy of various anaesthetic agents given around the time of formalin administration in inhibiting the subsequent pain-related behaviour, known as the phase 2 formalin response [2]. The phase 2 formalin response consists of complex pain-related behaviour, including licking of and flinching with the affected paw, which occurs 10–60 min after administration of formalin. This latter phase of pain behaviour can be distinguished pharmacologically from the first phase of paw flinching that immediately follows formalin injection into the paw, in that activation of spinal cord NMDA receptor is critical to the second phase, but not first phase of flinching. In contrast, the first phase occurs within the first 5 min of administration of formalin and has been shown to be sensitive to AMPA antagonists. Activation of the NMDA receptor has, in order studies, also been shown to mediate sensitization of individual spinal cord neurones (including "windup") and also to mediate enhancement of spinal cord reflexes [3].

In their study, O'Connor and Abram gave 1 MAC of a volatile anaesthetic agent or 70% nitrous oxide, or propofol (initially 10 mg kg^{-1} and then another 3 mg kg^{-1}, 1 min after formalin) before and during the period of expected phase 1 flinching. They showed that there was suppression of phase 2 flinching with this pre-emptive treatment and so they inferred that spinal cord sensitization had been suppressed (the only exception was that pre-emptive halothane and nitrous oxide given together did not prevent phase 2 flinching). The implications are that conventional anaesthesia does protect the spinal cord during surgery. However, when one looks for other evidence for inhibition of spinal cord sensitization by conventional doses of anaesthetics, the results are conflicting and often depend on the end-point being used. For example, in other studies of formalin-evoked flinching, Abram and Yaksh have shown that even 2.5% isoflurane only reduced phase 2 flinching by 35% when given pre-emptively (and, incidentally, in this study the addition of nitrous oxide to isoflurane abolished this benefit) while intrathecal morphine reduced flinching by 80% [4]. However, in another study, Abram and Olsen found that pre-emptive high-dose systemic opioids did not reduce phase 2 flinching [5]. As for propofol, other studies have not reproduced the findings of O'Connor and Abram [2] in that pre-emptive propofol 10–20 mg kg^{-1} did not reduce phase 2 flinching [6, 7]. Barbiturates similarly show variable efficacy in inhibiting spinal cord sensitization [6–8]. Abram and Yaksh [4] also point out that many of the studies that examined C-fibre induced spinal sensitization were carried out under surgical plane of anaesthesia [9].

Clinical studies have shown that a simple noxious stimulus-evoked reflex in volunteers was inhibited by 0.25–0.5% end-tidal isoflurane. However, repetition (five times at 2 Hz) of the same nociceptive stimulus caused facilitation of the nociceptive reflex and required 1–1.5% isoflurane to suppress it (and the authors pointed out that this dose is similar to the MAC of isoflurane). The authors then suggested that even this higher dose of isoflurane alone would not be adequate for inhibiting surgically evoked excitability in actual operations [10].

Those agents that are generally accepted to produce that state we call anaesthesia were never chosen for their analgesic potential. Several end-points have been used to define an adequate dose of anaesthetic, including loss of consciousness, inhibition of memory formation, lack of intraoperative movement, etc. However, when the results of studies examining more analgesic end-points for conventional anaesthetics are analysed, we find confusing and seemingly contradictory examples, as discussed above. This is because clinically accepted doses of anaesthetics have only moderate ability, at best, to inhibit (i) primary afferent input, (ii) the development of spinal cord sensitization and (iii) short- and long-term pain perception. Fortunately, perhaps conventional anaesthetics do show some analgesic effects, including NMDA receptor blocking activity, but this is unlikely to be contributing to their anaesthetic effect [11].

The purpose of the articles to which O'Connor and Abram refer, is to show that by using immediate early genes as end-points, noxious stimulation still enters the spinal cord during seemingly adequate anaesthesia (see references in [1]). It is not surprising that clinical studies of pre-emptive analgesia show little effect when the agents we use are not particularly good at doing what we ask of them, that is protecting the spinal cord against incoming afferent stimulation. For example it has been demonstrated previously that radically different outcomes in terms of long-term pain behaviour can be produced experimentally with different adjuncts to isoflurane anaesthesia (α_2 agonists, NMDA antagonists, peripheral blocks with local anaesthetic but interestingly, not μ agonists) despite similar lack of responsiveness during anaesthesia [12, 13]. Furthermore, as discussed previously, the ability to suppress *fos* expression by these adjuncts parallels these behavioural outcomes (see references in [1] and also Munglani, Fleming and Hunt, data submitted for publication).

As Abram and Olsen have previously written: "there is a dichotomy between behavioural response to a noxious stimulus and the development of enhanced responsiveness". Furthermore, Abram and Yaksh concluded "that the anesthetised state, as defined by loss of consciousness, or lack of motor response, may be disassociated from the processes leading to post injury facilitation" [4] an observation recently re-emphasized by Goto, Marota and Crosby [14].

As anaesthetists we pride ourselves on producing a state of anaesthesia which includes loss of consciousness, lack of memory formation and minimal autonomic activity. However, the evidence is that conventional anaesthetics (including μ agonists) do not adequately inhibit the longer term consequences of painful stimulation for the patient. Electrophysiological and immediate early gene studies suggest that we need to radically re-think what are our goals for anaesthesia and how we are to achieve them.

Spinal anaesthesia for Caesarean section

Sir,—We read with interest the letter from Stoneham and Souter on spinal anaesthesia for Caesarean section in women with incomplete extradural analgesia [1]. We congratulate them on their excellent results in 12 such patients, none of whom developed a sensory block above T3. Whether the results in this small series of patients implies that this is a safe technique is still dubious, especially in the face of the frequency of case reports of unexpectedly high spinal block associated with pre-existing extradural block (references [2–7] in Stoneham and Souter's communication).

We take issue with one aspect of their methods. In the list of indications for performing spinal anaesthesia in the presence of a pre-existing extradural block, they included patient(s) in whom the urgency of the situation was considered not to allow time for extension of the extradural block. They then described their technique which involves not preparing the patient for surgery until 20 min after spinal injection. Therefore, the time taken to have the patient ready for surgery is 20 min in addition to the time taken to transfer the patient to theatre, position the patient and perform the spinal anaesthetic. Our technique of choice in this group of patients is to extend the extradural block using an alkalinized mixture similar to that described by Fernando and Jones [2], namely 0.5% bupivacaine 10 ml, 2% lignocaine 10 ml, 1 ml of adrenaline 1 in 10000 (resulting in a final concentration of slightly less than 1 in 200000) and 2 ml of preservative-free 8.4% sodium bicarbonate. Although we have no audit of our own patients on the time taken for extension of the block to an acceptable height, this time is certainly less than 20 min. Using a similar mixture, Fernando and Jones found that the mean time to achieve sensory block T4–S5 in a group of 10 patients was 12.7 min (range 10–14 min) [2]. These patients were undergoing elective Caesarean section and thus had no pre-existing extradural block.

We would advocate the above technique for emergency Caesarean section as it provides suitable surgical anaesthesia without the patient undergoing an additional invasive procedure, that is performance of a spinal anaesthetic and the attendant risks thereof, and achieves this more rapidly than the technique described by Stoneham and Souter.

Sir,—We read with interest the study by Stoneham and Souter [1]. There is a lack of data on the safety and dose requirements of subarachnoid anaesthesia in women undergoing emergency Caesarean section after extradural analgesia for labour. Therefore, we have recently conducted an audit in order to produce a regimen for the management of these patients in our unit. During the 5-yr period 1990–1994, 30 such patients were identified. There were a variety of reasons for subarachnoid block; 21 cases had inadequate quality of extradural block, the extradural catheter had recently become displaced in eight patients and in the remaining patient there was inadequate time for extension of the extradural. The dose varied between 2 and 3.5 ml of heavy 0.5% bupivacaine, with 17 patients receiving 2.75 ml or more. Four patients also received subarachnoid fentanyl. In 12 cases the injection was given with the patient in the lateral position. We believe the variation in dose and position reflects individual anaesthetist's usual practice. The upper level of the block was recorded in only 16 patients. This varied from T1 to T5, with no correlation with either dose of bupivacaine or position of the patient during injection. In those patients where no block height was recorded, there was no evidence of an abnormally high block. Two of the four patients who received less than 2.5 ml of 0.5% heavy bupivacaine required supplementary analgesia (one general anaesthesia and one alfentanil and nitrous oxide–oxygen). This compared with only two patients requiring supplementation (both alfentanil alone) of the other 26 patients who had received bupivacaine 2.5 ml or more. Three of the four patients requiring additional analgesia had an adequate block height documented before surgery; there was no documented block height recorded for the remaining patient.

As a result of our findings, we have recommended in our unit that patients requiring subarachnoid anaesthesia for Caesarean section after extradural analgesia during labour should have subarachnoid block performed in the anaesthetist's preferred position, using 2.5 ml of heavy 0.5% bupivacaine. Careful attention to positioning, as recommended by Stoneham and Souter, should occur whenever subarachnoid block is given, regardless of whether or not the patient has previously received extradural analgesia. Neither we nor Stoneham and Souter have conclusively demonstrated the safety of the technique and we do not know the incidence of high block, which may be no greater than for subarachnoid block in the absence of pre-existing extradural blocks. We believe, however, unlike the recommendation by Kick and Bohrer [2], that reducing the dose of bupivacaine below our recommendation carries a significant risk of inadequate block.

2. Kick O, Bohrer H. Unexpectedly high spinal anaesthesia following failed extradural anaesthesia for Caesarean section. *Anaesthesia* 1993; **48**: 271.

Sir,—We agree with Drs Foster and Rogers that the technique described by Fernando and Jones of extending an extradural block may be more appropriate than subjecting the patient to the additional risks of a spinal anaesthetic if there is no evidence that the extradural is inadequate. There were two patients in our group of 12 who had unilateral extradural blocks in whom it was felt that there was insufficient time to manufacture a reliable extradural block.

In our limited study, we set out to investigate the unusual situation of women with inadequate extradural blocks who require a regional anaesthetic technique for Caesarean section. Since writing our letter to the *British Journal of Anaesthesia*, there has been further anaesthetic correspondence on this matter [1, 2] recommending that spinal anaesthesia should be avoided under these circumstances until further work has been done. We intended to show that it is possible to perform spinal anaesthesia in patients who have had previous, recent extradural analgesia provided that rigorous care is paid to the positioning of the patient, although of course we are not attempting to suggest that it is safe from the results of studying such small numbers of patients.

The 30 patients described by Drs Vickers and Wilkey are further evidence that it is possible to administer spinal anaesthesia safely in these circumstances, although information on the dose of local anaesthetic, or opioid agents, or both, administered into the extradural space, or how recently they had been given in these 30 patients would have been useful. In addition, we believe that the position of the patient during the siting of the spinal may be less important in determining the outcome than the position of the patient while the spinal anaesthetic develops. Nine of the 10 case reports of unexpectedly high spinal block after failed extradural analgesia were placed in the wedged supine position immediately after spinal injection [3–9]. It is known that the supine hypotensive syndrome is not completely abolished in the wedged supine position [10]. The intriguing possibility arises that partial maternal aortocaval compression in the wedged supine position, leading to extradural venous engorgement, may result in unpredictably high blocks after spinal anaesthesia, particularly where there is already exogenous fluid in the extradural space as in all of these case reports. We are investigating the possibility that positioning patients in the wedged supine position while a spinal anaesthetic is developing may produce a more unpredictable final block height than the lateral position and this may be exacerbated if there is already fluid in the extradural space.

BOOK REVIEWS

Regional Anesthesia: An Illustrated Procedural Guide, 2nd Edn. M. F. Mulroy (editor). Published by Little, Brown & Co, Boston. Pp. 313; indexed; illustrated. Price £47.00.

This book aims to provide a practical manual of regional anaesthesia and follows the common pattern of such texts, with the first five chapters dealing with basic physiology and pharmacology, handling of the patient and complications, and equipment. Thereafter specific techniques are discussed individually with explanation of the relevant anatomy and specific complications. The final chapters deal with subspecialty areas, including acute and chronic pain management.

This book is more than just a practical manual. There is a wealth of background information, each chapter is well referenced and all the commonly used regional techniques are covered. The text is well written and easy to follow. The illustrations are mostly black and white with the occasional use of one additional colour. These are certainly adequate for the purpose but no more, and do not compare favourably with other texts. As one might expect, the emphasis is based on North American practice, for example for spinal anaesthesia most of the discussion is about amethocaine, with bupivacaine only mentioned in passing. For i.v. regional anaesthesia the suggested drug is lignocaine and the use of prilocaine or bupivacaine is mentioned. Although the potential problems of the latter are mentioned I would expect stronger criticism in the UK. The book also follows the example of others by including chapters on the use of regional anaesthetic techniques in pain management. This may be appropriate for acute pain, where regional techniques have much to offer, although I did wonder why a section on i.v. patient-controlled analgesia was included. It is less relevant for chronic pain management where regional techniques play a smaller part and other issues such as proper assessment and the decision if and when to use a regional technique assume far greater significance. I hope that these sections in textbooks of regional anaesthesia do not encourage clinicians to dabble in pain management on the basis of ability with a few regional techniques.

There are a large number of up-to-date texts on regional anaesthesia currently available and it will be interesting to see if there really is still a gap in the market. A number of medical texts do not cross the Atlantic well and I think that this will be among them. It is ring bound, presumably so that it can be laid open flat for reference and I hope that this will not encourage self teaching by an individual who is looking at it as the block is performed. I think it unlikely that this format would be suitable for a library or departmental copy as it may not prove very robust. It could not be recommended for trainees and I doubt that it will cope with the competition for a place in departmental libraries, although some enthusiasts for regional anaesthesia may like the style and wish to have their own copy.

W. A. Chambers

ABC of Brainstem Death, 2nd Edn. C. Pallis and D. H. Harley. Published by BMJ Publishing Group, London. Pp. 52; indexed; illustrated. Price £10.95.

The second edition of *ABC of Brainstem Death* has appeared 12 yr after the first. In response to the *Panorama* programme "Transplants: are the Donors Really Dead?" in 1980, a great deal of alarm was spread to the general public, and subsequently, in 1983, the first edition of this text by Christopher Pallis was published. The first edition was an excellent collection of BMJ articles which discussed the definition of death, evolution of thinking towards the concepts of brain death and brainstem death and practical aspects of diagnosis.

The original text has been updated but presented in the same readable fashion with historical, technical and cartoon illustrations which clarify the text. Since that publication it has remained clearly established that no patient in apnoeic coma declared brainstem dead according to the UK criteria ever regained consciousness. Moreover, asystole occurred within a short period of time after the diagnosis was made. This new edition, therefore, has extended considerations of the brainstem dead patient as an organ donor and it also tackles the issue of persistent vegetative state.

UK practice is put into perspective by comparison with approaches to this diagnosis in the rest of the world. The authors correctly observe that the position in the UK is often misunderstood as, despite the endorsement by the Department of Health and the Conference of Medical Royal Colleges and their Faculties, there is no legal status to the UK Code of Practice. The code has never been tested in a court of law, although it has been given tacit support in a House of Lords Select Committee.

The second edition contains useful advice on the management of organ donors and also addresses the issue of elective ventilation. Although many problems are identified, specifically that the Department of Health has accepted legal advice that treatment which is not directly for the patient's benefit may not be lawful, there is no guidance to the reader from the authors on this issue. Perhaps that is why, yet again, this matter has been referred to a Parliamentary Select Committee.

This is an excellent text heartily recommended for all those who are involved with the diagnosis of death and in the management of organ donors.

S. M. Willatts

Recent Advances in Anaesthesia and Analgesia – 19. A. P. Adams and J. N. Cashman (editors). Published by Churchill Livingstone, Edinburgh. Pp. 210; indexed; illustrated. Price £27.95.

The appearance of the 19th in the series of *Recent Advances* is as true a testament to the need for the regular publication of up-to-date reviews of recent developments in our specialty as it is a tribute to the quality of past editions. This latest volume sees a change in editorial personnel, with Dr J. N. Cashman replacing Dr R. S. Atkinson, who was involved with the previous seven, a contribution to which Professor Adams pays full tribute in his foreword.

This edition contains 11 reviews of topical subjects, all clinically relevant, but ranging from very detailed consideration of a small subject (R-R intervals and depth of anaesthesia) to very broad examination of clinical technique (anaesthesia and analgesia for Caesarean section). Each review is commendably concise yet covers the subject comprehensively and is fully referenced. The great majority of authors are UK-based anaesthetists, but one notable exception is Dr R. Green from Farnborough who has contributed a very thought-provoking review on "The psychology of human error", although his numerous references to aviation incidents did make me regret the decision to start reading the book during my plane journey to Sydney for the World Congress!

The commendable brevity, but completeness, of each review, together with the modest price should make this required reading for almost every anaesthetist, and certainly every final fellowship candidate. This does not imply that I do not have criticisms. While one can accept that an expert in a field will be enthusiastic about the subject, I am concerned that the editors should state dogmatically in their preface that "every anaesthetist should be proficient in fibreoptic intubation", particularly as the relevant review admits that this is not the case and recognizes the difficulties. I was also disappointed by the quality of the English in some of the contributions. Style is a matter of preference, and it would be a dull world if we all wrote in exactly the same way, but I cannot consider use of the word "undermedicated" as anything but horrible!

However, these are minor complaints about what is, overall, a very useful volume. The true mark of an expert in any field is that he recognizes what he does not know, and virtually all of the authors are honest with regard to their subjects. It is particularly refreshing to read a review (by Dr D. Justins) of chronic pain that is so honest as to admit that most current therapeutic options are really no more than variations on willow bark and poppy! Buy this book.

BRITISH JOURNAL OF ANAESTHESIA

VOLUME 77, No. 3 SEPTEMBER 1996

EDITORIAL I

Complications of hysteroscopic treatments of menorrhagia

Menstrual disorders are extremely common, and approximately 22% of healthy women complain of menorrhagia[1]. However, such complaints are subjective and it is well recognized that many women are poor judges of their menstrual flow. Only 40% of those complaining of heavy periods have menorrhagia, as defined by measured blood losses exceeding 80 ml for each menstruation[2]. This may account in part for the lack of efficacy and patient acceptability of many of the drugs used for the treatment of menorrhagia. Consequently, many patients are referred to gynaecology clinics for surgical management of their problems, menorrhagia accounting for approximately 15% of gynaecological referrals[3].

Before the advent of minimally invasive techniques in the management of menorrhagia, hysterectomy was the surgical treatment of choice; the hysterectomy rate by the age of 55 yr in the UK was approximately 20%[4]. As early as the 1980s there has been increasing enthusiasm for endoscopic techniques aimed at destroying or ablating the endometrium for the treatment of menorrhagia. Three techniques have gained popularity, all using a hysteroscope in conjunction with fluid infused into the uterine cavity under pressure to distend it and give the operator a clear view within the uterus. Electrodiathermy is used in two of the methods, with the endometrium being resected with a wire loop (resection) or ablated with a "rollerball" (coagulation). For the third technique a Nd-YAG laser is used to ablate the endometrium. Although the three techniques destroy the endometrium in different ways, collectively they are termed transcervical endometrial ablation (TCEA).

In comparison with hysterectomy, hysteroscopic techniques are simple, require less operating time and the time for the patient to recover fully is substantially reduced. However, there is concern that some serious complications may occur during hysteroscopic surgery and it is important that both surgeons and anaesthetists are aware of this morbidity, especially as many of these procedures take place as day-cases. The main complications of TCEA are postoperative haemorrhage, fluid absorption, infection and uterine perforation.

Postoperative haemorrhage occurs in up to 2.5% of cases[5–7], occasionally being severe enough to require blood transfusion. Haemostasis may be produced by inserting a Foley catheter into the uterine cavity and inflating the balloon to compress the vessels—usually a period of 4–8 h is adequate.

Fluid overload is a potentially serious complication of TCEA. Absorption of excessive amount of irrigation fluid during operation directly through blood vessels opened up by the resection may lead to the syndrome familiar to urologists and anaesthetists as transurethral resection of the prostate (TURP) syndrome. Fluid entering the peritoneal cavity though patent Fallopian tubes may also be absorbed into the circulation but the magnitude or significance of this fluid absorption is not clear. One study has shown a 20% reduction in fluid absorption in women with occluded Fallopian tubes caused by prior sterilization[8]. The incidence of fluid overload (defined as losses exceeding 2000 ml) in TCEA varies from 1 to 5%[9–11]. The development of fluid overload is influenced by several factors, including type of irrigation fluid, infusion pressure, vascularity of the uterus, duration of surgery and surgical technique.

Electrodiathermy requires the use of solutions which do not conduct electricity. These include 1.5% glycine, 5% sorbitol and 5% mannitol[12]. The most commonly used irrigation fluid is 1.5% glycine. It has good optical qualities but is hypotonic (osmolality of 1.5% glycine is 188 mosmol kg^{-1}) and absorption into the circulation may cause fluid overload, hyponatraemia, pulmonary oedema and cerebral oedema. Hyperglycinaemia and hyperammonaemia may occur with the use of 1.5% glycine. Hyperglycinaemia has been reported as the cause of transient blindness in some patients undergoing TURP[13 14]. Glycine is broken down in the liver into ammonia and oxalate; ammonia may produce deterioration of cerebral function after endometrial ablation when the blood concentration of ammonia exceeds 150 μmol litre^{-1} (normal 11–35 μmol litre^{-1})[15 16]. In addition, transient arterial oxygen desaturation, hypercapnia and coagulopathy have been reported[17].

Sorbitol 5% is isotonic with a short half-life of 35 min but it causes toffee-like deposits on the electrode and this may make the resection technically difficult. Consequently, it is seldom used. Mannitol 5%, although isotonic, has a long half-life and is also seldom used; it may cause visual distortion and crystallization on instruments[18]. Normal saline may be used only when laser treatment is contemplated and there is no danger of electrical conduction. It is isotonic and optically clear but it may also lead to fluid overload and pulmonary oedema if absorbed in large quantities. Carbon dioxide may be used for distension during diagnostic hysteroscopy, but although excellent vision is provided, it cannot be used in conjunction with operative hysteroscopy as these procedures open vessels through which carbon dioxide can gain access to the circulation and cause pulmonary embolus[18]. Production of smoke during resection may also impair vision when carbon dioxide is used for distension.

The uterine cavity has a low compliance and high irrigation pressures are required during endometrial ablation. Although views of the uterine cavity are possible with irrigation pressures of 40 mm Hg, it has been shown that pressures of 100–110 mm Hg may be required to see the tubal orifices[19]. The intrauterine pressure (IUP) attained during endometrial laser ablation may influence the amount of fluid absorbed and it has been suggested that this should be limited to 60 mm Hg[20]. Various methods are used to introduce fluid into the uterine cavity under some type of pressure control. The simplest method uses a gravity fed system. This consists of a 3-litre bag containing fluid and held 1 m above the uterus, thus providing sufficient pressure for uterine distension. Pressurizing the infusion bag is an alternative and relatively cheap method of controlling uterine pressure. Peristaltic pumps, although considerably more expensive, have been used widely to provide constant flow. These give excellent visual conditions but may be associated with a progressive increase in IUP. With such constant flow variable pressure pumps, excess fluid absorption is a particular problem. This problem can be reduced by using pressure controlled pumps[21]. In a study by Hasham and colleagues[22], a hysterogram was obtained during endometrial laser ablation and this showed no absorption of irrigation fluid into the venous system at an IUP of 70 mm Hg, while at 150 mm Hg contrast medium was seen entering the uterine venous system.

Less absorption of fluid may occur if resection takes place when the endometrium is relatively avascular, hence it is preferable to carry out this procedure during the mid-proliferative phase of the menstrual cycle. Some gynaecologists prefer to prescribe some type of hormonal preparation with danazol, progestogen or gonadotrophin-releasing hormone (GnRH) agonists to make the endometrium atrophic[20 23].

Absorption of fluid may be influenced by the duration of the resection. It has been suggested that reduction of operating time to 1 h or less may minimize the development of TURP syndrome. However, as with TURP syndrome, the risk of developing fluid overload in TCEA is not always related to the duration of surgery; the syndrome may develop in 10–15 min[24 25]. Surgical technique also influences the development of fluid overload. Of the three methods used, endometrial rollerball coagulation carries least risk[26] as there is no cutting of blood vessels or tissue and thus there is less fluid absorption and haemorrhage compared with the two other techniques.

The amount of fluid absorbed by the patient may be calculated as the volume of fluid infused into the uterine cavity minus the volume which passes out through the cervix into the collection system and on to drapes and swabs. This is defined as the fluid deficit. It is important to monitor fluid deficit continuously in order to provide an early estimation of the rate of fluid absorption. Unfortunately, there is no simple, accurate method of measuring fluid deficit, although volumetric and gravimetric methods are commonly used. In the simple volumetric method, the difference between the volume of irrigation fluid used and the volume recovered is measured. A more complex but accurate volumetric method has been described by Hahn, Berlin and Lewenhaupt[27]; in this method 3-litre bags are weighed accurately before and after use. During hysteroscopy they are placed 60 cm above the centre of the surgical field. The first bag is used to fill the irrigation system before the operation is started. A volumetric irrigating fluid balance is obtained every 10 min during operation: the irrigation fluid inlet is closed, the uterus emptied and the irrigating fluid bag and the collecting bag replaced. Blood loss is calculated from the haemoglobin concentration of the irrigation fluid. Because this method is complex, it is less applicable to routine use and is more useful for research. In contrast, the gravimetric method is simple in concept but involves weighing the patient either on the operating table or the bed[28] and is therefore cumbersome and rarely used.

In 1991, Hulten and colleagues described a simple, non-invasive and continuous method of monitoring irrigation fluid absorption during TURP using ethanol[29]. The irrigation fluid is tagged with ethanol and expired breath ethanol concentration measured using an alcohol analyser. Glycine 1.5% with 1% ethanol (Baxter Health Care Ltd, UK) is available in the UK. Blood ethanol concentrations reflect the balance between the rate of entry into the circulation and the rate of removal, redistribution and elimination. Nomograms have been developed which relate ethanol concentration in expired gas to the volumes of irrigant fluid absorbed and the resulting reduction in serum sodium concentration during TURP surgery. The same evaluations of correlations between expired ethanol concentration, serum sodium concentration and volume of irrigant absorbed have also been made in 62 patients undergoing TCEA[28 30]. Using these nomograms it was found that the volume of irrigant absorbed during TCEA produced about a 10% greater increase in expired ethanol concentration and a 40% greater reduction in sodium concentration than occurs during TURP. It is difficult to account for these differences and clearly a larger bank of data is required in order to develop nomograms for patients undergoing endometrial ablation. At present, therefore, fluid deficit is the best indicator of fluid overload during TCEA. It is recommended that surgery is stopped as soon as possible when the deficit is 1000–2000 ml and immediately when the deficit exceeds 2000 ml[31]. Some authors have suggested that when a 500-ml deficit is noted, serum electrolyte concentrations should be measured to check sodium concentrations and if a 1000 ml deficit occurs, frusemide 20 mg should be administered i.v.[18].

The syndrome arising from absorption of large volumes of irrigation fluid has been described and studied extensively in relation to TURP syndrome[32 33]. Circulatory overload may cause acute left ventricular failure, pulmonary oedema and hypoxia. Hyponatraemia causes cerebral oedema; if the serum sodium concentration decreases to less than 120 mmol litre^{-1}, agitation, nausea, vomiting, headaches and confusion usually occur and subsequently there may be seizures, coma, respiratory arrest and even death[34]. Plasma sodium concentration and osmolality should be monitored closely if clinical signs occur suggestive of the syndrome. As a guide to clinical management it has been suggested that a serum sodium concentration of 120 mmol litre^{-1} be the boundary between mild and severe hyponatraemia[33]: mild hyponatraemia should be treated with fluid restriction and diuretics. Although 3–5% hypertonic saline 200–500 ml over 4 h has been recommended[35] for the treatment of severe hyponatraemia, there is concern about its use. If hyponatraemia is corrected too rapidly, it may lead to an abrupt decrease in cerebral blood volume leading to intracranial haemorrhage[36]. Excessively rapid correction of chronic hyponatraemia may cause cerebral demyelination lesions (central pontine myelinolysis)[37]; however, the pathophysiology of this syndrome differs from that of acute hyponatraemia and demyelinating lesions have not yet been described in either the TURP[32] or TCEA syndrome. Diagnosis of hyponatraemia during anaesthesia is aided by development of electrocardiographic changes such as wide QRS complexes and ST-elevation, progressing to ventricular tachycardia and ventricular fibrillation[32].

Although it is standard practice to use prophylactic antibiotics, postoperative infection occurs in up to 2% of patients undergoing TCEA; this rate is substantially less than that in women undergoing hysterectomy[38]. Uterine perforation complicates up to 4% of endometrial resections[7–11] but this may be less with the laser than the wireloop or rollerball techniques[5]. In most reports, perforation has occurred during insertion of either a sound or endoscope through the cervix. Such perforations are unlikely to lead to damage of other structures provided the complication is recognized and the procedure is abandoned. If perforations occur while the laser or diathermy is in use there may be damage to large vessels, bladder or bowel. If such damage is feared, laparotomy is usually necessary rather than laparoscopy as the latter may not easily reveal the site of any damage.

There have been three randomized controlled trials comparing hysteroscopic methods of managing menorrhagia with abdominal hysterectomy[11 38 39]. All reported substantially decreased operating times for the hysteroscopic methods, and an average hospital stay of 1 day compared with 7 days for hysterectomy. Time to full recovery (defined as time taken to return to work) was 2–3 weeks compared with 2–3 months for the hysterectomy group. Complications were significantly fewer in the endoscopic group, with 4–8% of patients developing complications compared with 46% of the hysterectomy group[11]. However, in one study, long-term follow up revealed that women undergoing hysterectomy were generally more satisfied with treatment; 89% of patients were satisfied compared with 78% in the endoscopic group[40]. Of those allocated to hysteroscopic treatment, 12% required repeated endoscopic treatment for continued menorrhagia and 16% required hysterectomy within 2 yr. Analysis of the cost-benefit ratio was undertaken in this study[40]; at 4 months endoscopic therapy as a percentage of mean total cost of hysterectomy was 53%, but by 2 yr, taking into account additional therapy, the gap had narrowed to 71%. Longer term follow-up is awaited to determine if the cost benefit of endoscopic therapy persists.

Although the benefits of endometrial ablation both to the patient and in financial terms are unclear, there is no doubt that hysteroscopic techniques for managing menorrhagia are increasingly popular with both patients and gynaecologists. However, these techniques are still in an evolutionary stage. Most TCEA procedures are performed as day-cases and it is important for anaesthetists to be aware of the immediate complications that can occur. Patients who are at risk of developing complications should be admitted for observation as inpatients. While complications are uncommon after the patient leaves hospital, it is important that the patient and general practitioners are fully aware of potential late problems.

EDITORIAL II

What future is there for predicting difficult intubation?

With the publication of another study on the accuracy of clinical bedside tests to predict difficulty with intubation[1] it is perhaps reasonable to question what impact these studies have had on our understanding of difficult intubation and what lies in the future in this field. One of the problems with many of these studies it that there has been a lack of reproducibility and perhaps a tendency to modify the tests accordingly. Because of the diversity of factors involved, the desire to have a simple bedside test to predict almost all cases of difficulty may be considered unduly optimistic. Presumably, Wilson and colleagues started with this hope when they proposed a scheme specifically to assess a combination of factors[2]. Another major problem in this area is the lack of universal agreement on what is implied by "difficult"[3].

Bellhouse and Doré[4] derived a predictive formula based on a retrospective radiological survey of subjects who presented difficulty in tracheal intubation. More importantly, they claimed that the most important features relevant to difficulty were reduced atlanto–occipital extension, reduced mandibular space and increased anteroposterior thickness of the tongue. Recent studies have focused most attention on the Mallampati test[5], thyromental distance[6] and sternomental distance[7]. The Mallampati test involves the relative size of the tongue by observation of the degree to which it appears to fill the mouth (i.e. obscure the view of the soft palate). The two other tests fit with the concept of space for the tongue within the constraints of the mandible and the degree to which the airway is opened by adequate extension of the neck. Many studies have supported their individual or combined efficacy[8–11], but each test has also been questioned or received only qualified support by others[1–3 12–14]. Reproducibility of the Mallampati test in particular has been questioned and the relevant issues were well reviewed in the study of Pilkington and colleagues who made photographic assessments for Mallampati gradings during pregnancy[15].

While clinical studies on prediction of difficulty in intubation have been published on a regular basis, a parallel branch of clinical and theoretical research has continued, following on from another aspect of Bellhouse's work, that is to further understand and model the mechanisms of difficulty[16–20]. This culminated in a two-dimensional mathematical model for osseous factors in difficult intubation[21]. At the time it was thought that verification of this model would be daunting. The main principle for appropriate use of the traditional Macintosh laryngoscope is negotiation of the curved blade around and beyond the base of the tongue to make contact with the hyoid bone in order to elevate the epiglottis. The hyoid can be lifted forward if the blade tip is at least in contact with the lesser horns of they hyoid, but shortening of the hyoepiglottic ligament maximizes elevation of the epiglottis and this is achieved when the blade tip is directly behind the body of the hyoid and particularly when it is below this level[16]. Apart from when there is severely limited mouth opening, the usual obstruction to adequate exposure of the larynx is the tongue[4].

From the point of view of the two-dimensional model, the main considerations are the relative alignment of two intersecting straight lines[21]. The first line extends from the tip of the upper incisors to an anterior airway point immediately above the laryngeal inlet and may be considered to represent the optimal natural eyeline. The second is also in the median plan and represents the jaw as an imaginary line from the internal midpoint of the symphysis of the mandible to an imaginary point midway between the condyles. The relationship between these lines can be used to describe anatomical variations and also dynamic changes which occur on mouth opening or change in head and neck position, or both. A "final common pathway" for most causes of difficulty with intubation has been suggested to be the relative lack of space into which the tongue remaining anterior to the laryngoscope blade (the "minimal residual volume") can be displaced in order to view the larynx[19]. This space is represented in the model by the triangle demarcated by the jaw line superiorly and the optimal natural eyeline posteriorly. When this space is severely restricted, attempts to perform conventional laryngoscopy with a Macintosh blade have been shown to force the tongue down into the pharynx with the result that the epiglottis can become fixed against the posterior pharyngeal wall. This has been termed the "peardrop effect", on the basis of the way in which the minimal residual volume becomes distorted under these circumstances. In this context the actual laryngoscopy blade used is important and an appropriate analysis of the blade shape was suggested by Marks, Hancock and Charters[22].

There is a paradox in many of these considerations in that, to anaesthetists who regularly deal with the most difficult intubations in their routine clinical practice, much of what has already been described is fairly irrelevant. Dealing with tumours of the supraglottic region and base of tongue represents the most challenging intubation problem and yet it is very unlikely that predictions of degree of difficulty for such cases would be fruitful. Even benign soft tissue problems such as vallecula cysts may cause severe laryngoscopic embarrassment because they interfere with the usual mechanism of laryngoscopy (i.e. the blade tip must enter the vallecula) or push the epiglottis posteriorly, making it difficult to reposition the blade tip below the epiglottis to lift it up. These patients tend to be asymptomatic even when the cysts are fairly large[23]. Radiation changes may also have an important effect in decreasing soft tissue mobility but the history and preoperative clinical findings should indicate the likely effect in these cases. Stylohyoid ligament calcification is another unusual cause of difficulty but it is important in understanding the mechanisms of intubation as it limits forward movement of the hyoid which is required to elevate the epiglottis[19]. The prediction tests would not be expected to be sensitive to these uncommon but important conditions nor would the mathematical model, but then the model specifically describes osseous factors only.

An important discovery with the intubation model was the prediction of a previously unreported mechanism of difficulty termed the "hi-slung mandible". With respect to intubation, it is the lower compartment of the temporomandibular joint which needs to be considered because the condyles are naturally in this position when the mouth opens and when the laryngoscope is pulling the hyoid forward. In the condition of "hi-slung mandible", the temporomandibular joint is abnormally anterior and rostral. When a patient is positioned in the "standard intubating position"[17] with the laryngoscope exposing the larynx, the optimal natural eyeline and jaw line intersect at approximately 90° [21]. This implies that if the jaw is considered to simply rotate around the condyles (given that it is already in the lower compartment of the temporomandibular joint), the jaw line is as far in front of the natural optimal eyeline as possible. On the other hand, if the centre of rotation is higher and more anterior than normal, as with the "hi-slung mandible", opening the jaw sufficiently to admit a laryngoscope blade will ensure that the jaw line/optimal natural eyeline intersection is significantly less than 90°. Therefore, even if jaw translation appears normal with the mouth closed, the act of mouth opening in this condition makes the jaw fall back markedly so as to make it behave as if it were receded. The incidence of this phenomenon is unknown but examples have been cited and it may not be very uncommon. It would be expected that the currently popular predictive tests would not recognize this problem.

One unfortunate feature of most of the studies which have attempted to predict difficulty in intubation appear to be the inability to explain failures. This is perhaps understandable because of the requirement to examine large numbers of subjects in order to determine low failure rates and false positive predictions. This deficiency has been commented on previously[24]. The most important lesson from the intubation model is that factors combine to produce a net effect and it may be that adverse effects are counterbalanced to a greater effect by favourable ones. For example, absent upper incisors may make a severely receded jaw less of a problem but if prominent buck teeth occur in the presence of a receded jaw, the effect is likely to be considerably worse. In the model, this net effect on expected laryngeal exposure is measured as an "F" score which is directly related to the area of the triangular space below the mandible, as described above.

Bellhouse also described a new blade[25]. This was the first blade design to be related specifically to measurements and ideas derived from an analytical clinical study. The study on the function of various blade shapes by Marks, Hancock and Charters[22] was essentially descriptive but could be converted relatively easily to a computational form. It remains to be seen if this approach challenges further the position of the Macintosh blade as the optimal rigid design. At present the future for simple predictive bedside tests is speculative. It is clear from all the published work over the past decade that our understanding of the mechanisms of tracheal intubation have advanced substantially. As far as modelling is concerned, the future holds great potential. Three-dimensional computer imaging is already in existence and it may only be a short time before routine preoperative imaging of ENT/facio-maxillary patients can be presented to the anaesthetist in a virtual reality setting in which various alternative intubation techniques can be tried by simulation before taking the patient to the operating theatre.

CLINICAL INVESTIGATIONS

Sternomental distance as the sole predictor of difficult laryngoscopy in obstetric anaesthesia

S. A. L. Ramadhani, L. A. Mohamed, D.A. Rocke and E. Gouws

Summary

Sternomental distance and view at laryngoscopy were documented in 523 parturients undergoing elective or emergency Caesarean section under general anaesthesia. Eighteen (3.5%) had a grade III or IV laryngoscopic view (Cormack and Lehane's classification) and were classified as potentially difficult tracheal intubations. There was a significant difference between sternomental distance in those patients with a grade III or IV laryngoscopic view compared with those with a grade I or II (13.17 (SD 1.54) cm *vs* 14.3 (1.49) cm; P=0.0013). A sternomental distance of 13.5 cm or less with the head fully extended on the neck and the mouth closed provided, using discriminant analysis, the best cut-off point for predicting subsequent difficult laryngoscopy. A sternomental distance of 13.5 cm or less had a sensitivity, specificity, positive and negative predictive values of 66.7%, 71.1%, 7.6% and 98.4%, respectively. While there was no association between sternomental distance and age, weight, height or body mass index (BMI), there was a significant association between grade of laryngoscopy (III and IV) and older (P=0.049) and heavier (P=0.0495) mothers. The results suggest that while sternomental distance on its own may not be an adequate sole predictor of subsequent difficult laryngoscopy the measurement should be incorporated into a series of quick and simple preoperative tests. (*Br. J. Anaesth.* 1996;**77**:312–316)

Key words

Anaesthesia, obstetric. Anaesthetic techniques, laryngoscopy. Larynx, laryngoscopy. Intubation tracheal, difficult.

The most recent Report on Confidential Enquiries into Maternal Deaths in the UK has continued to highlight the relationship between maternal death and difficulty with tracheal intubation[1]. Because of the potentially serious consequences of failed tracheal intubation, considerable attention has focused on attempts to predict, at the preoperative assessment, patients in whom laryngoscopy and intubation will be difficult[2–8]. Only one of these studies[6] has dealt specifically with obstetric patients in whom the risk of difficult intubation is reported to be eight times greater than in the general surgical population[9]. One of the preoperative tests which should be undertaken by the anaesthetist is an assessment of head and neck mobility. In a recent large study in an obstetric population, Rocke and colleagues used the presence or absence of a short neck as a subjective indication of a likely reduction in atlanto–occipital extension[6]. More recently, Savva found that measurement of sternomental distance, a possible objective indicator of head and neck mobility, was the best of five preoperative tests[8]. Savva found that neither forward protrusion of the mandible nor interincisor gap were useful tests and also suggested that the modified Mallampati test and thyromental distance were neither sensitive nor specific enough for routine use, thus suggesting that sternomental distance should be used as the sole routine test. We were of the opinion however that it was most unlikely that a single test could be used. Nevertheless, and because few obstetric patients were included in the study of Savva, we decided to assess the value of sternomental distance as a sole predictor of difficult laryngoscopy in an obstetric population.

Patients and methods

Sternomental distance and subsequent direct laryngoscopy were recorded in a group of patients presenting for Caesarean section to the obstetric unit at Al Corniche Hospital, a regional obstetric, gynaecology and neonatal hospital. All anaesthesia staff participated after explanation of the study and the data collection form. The hospital undertakes approximately 9000 deliveries annually, and efforts were made to obtain data on as many patients as possible, including both emergency and elective cases. The study was conducted over an 8-month period from November 1, 1994 to June 30, 1995. For each patient the following data were recorded: age, weight, height and method of anaesthesia (general, spinal or extradural). In some cases the patient's weight and height were not available because of the emergency nature of admission.

Before anaesthesia, assessment was made of the airway. This included the ability of the patient to open her mouth, assessment of receding mandible or protruding upper teeth, and subjective assessment of

head and neck extension. While a view of the oropharynx was undertaken the result was not documented as the purpose of the study was to assess sternomental distance as the sole predictor. During the course of the airway assessment, sternomental distance was measured as the straight distance between the upper border of the manubrium sterni and the bony point of the mentum with the head in full extension and the mouth closed. A ruler was used and the distance measured was approximated to the nearest 0.5 cm. Where there were two anaesthetists assigned to the patient, sternomental distance was measured by one while the other performed laryngoscopy and intubation without knowledge of the measurement. Where only one anaesthetist was assigned to the patient, sternomental distance was measured by an operating department assistant trained to measure the distance in the standardized manner; again the intubating anaesthetist was unaware of the measurement.

After preoperative assessment, the anaesthetist was given the freedom to decide, in consultation with the patient, whether or not the patient should receive general or regional anaesthesia. Because of primarily cultural preferences for not being awake during surgery, the majority of patients chose general anaesthesia. Patients were transferred to the operating room while in the left lateral position, and 30 ml of sodium citrate 0.3 mol litre^{-1} were administered orally before transfer to the operating table. All elective cases also received oral ranitidine 150 mg the night before and the morning of surgery. The majority of emergency cases were given either oral ranitidine 150 mg if first admitted to the labour ward or ranitidine 50 mg i.v. if time allowed. After 3 min of preoxygenation, anaesthesia was induced with either thiopentone or etomidate followed by suxamethonium. Cricoid pressure was applied gradually as the patient lost consciousness.

Immediately after rapid-sequence induction, assessment was made of the view at laryngoscopy, as described by Cormack and Lehane[10]. The classification was as follows: grade I=most of the glottis visible; grade II=only the posterior extremity of the glottis visible; grade III=no part of the glottis visible, only the epiglottis; grade IV=not even the epiglottis visible. The best laryngoscopic view was obtained using a curved Macintosh laryngoscopic blade, with all patients anaesthetized, fully paralysed and in the sniffing position. Intubation was attempted either after cessation of fasciculations or if there were no fasciculations, when the anaesthetist considered jaw relaxation to be adequate. Cricoid pressure was maintained until the trachea was intubated, the cuff inflated and correct tube placement verified.

STATISTICAL ANALYSIS

Patient data are presented as mean (SD). Body mass index (BMI) was determined from weight (kg)/height^2 (m). Pearson's correlation coefficient or Student's unpaired t test was used to determine relationships between age, height, weight, BMI and either sternomental distance or laryngoscopic view. For analysis, laryngoscopic grade was grouped as "difficult" (grades III and IV) or "easy" (grades I and II). Student's unpaired t test was used to assess the significance of the difference in sternomental distance between the groups.

Subsequently, discriminant analysis was used to calculate the most accurate sternomental distance cut-off point for discriminating between the difficult and easy laryngoscopic groups. Sensitivity, specificity, positive and negative predictive values were calculated for this cut-off point (see table 1 for definitions). In addition, a receiver operator characteristic (ROC) curve was used to assess the predictive value of various cut-off points in the prediction of laryngoscopic grade. Logistic regression analysis was used to describe the association between laryngoscopic grade and sternomental distance and to predict the likelihood of a grade III or IV laryngoscopic view. Relative risk and 95% confidence intervals were calculated for the probability of grade III or IV specific cut-off points.

Results

During the study period of 8 months, 5520 mothers delivered in the obstetric unit at the hospital. Of these, 646 (11.7%) patients underwent either elective or emergency Caesarean section. Of the patients studied, 33 underwent operative delivery during either spinal or extradural anaesthesia; therefore, the general anaesthesia group comprised 613 patients and of these, data were collected from 523 patients, representing 85.3% of the obstetric surgical case load during the study period. The majority (73%) of these cases were emergencies. Mean age of the patients was 30.4 (range 15–50) yr, mean weight 78.2 (SD 16.05) kg and mean height 156 (6.47) cm. Mean BMI was 31.95 (5.73). There was no association between sternomental distance and age, weight, height or BMI

Table 1 Definitions of statistical terms

Sensitivity (true-positive fraction)	=	Number of difficult intubations correctly predicted Number of difficult intubations
Specificity	=	Number of easy intubations correctly predicted Number of easy intubations
False-positive fraction	=	1 − specificity
Positive predictive value	=	Number of difficult intubations correctly predicted Number of intubations predicted \to\be difficult
Negative predictive value	=	Number of easy intubations corrected predicted Number of intubations predicted \to \be easy

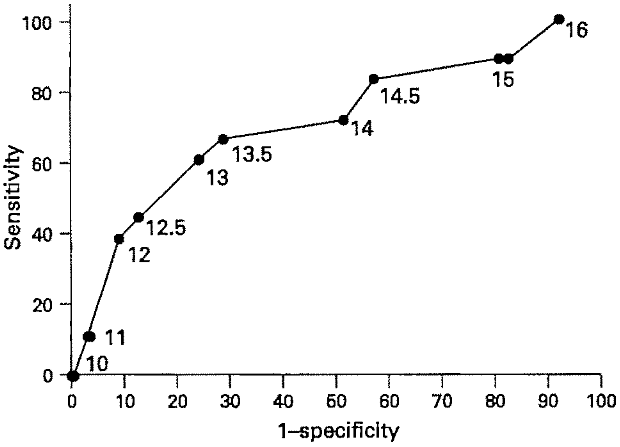

Figure 1 Receiver operating curve (sensitivity *vs* 1− specificity) to assess the predictive value of the various cut-off points in the prediction of laryngoscopic grades III and IV. Sternomental distances are shown and a distance of 13.5 cm proved to be the best cut-off point.

(Pearson's correlation coefficient, $r<0.3$). There was, however, a significant association between age and weight and difficult laryngoscopy (table 2). Patients who had a reduced laryngoscopic view were older and heavier. There were no significant differences in age, weight, height or BMI between the group of patients undergoing general anaesthesia and the group undergoing Caesarean section under regional anaesthesia. No patient had regional anaesthesia solely because of an assessment by the anaesthetist that tracheal intubation would be extremely difficult.

Mean sternomental distance was 14.28 (SD 1.50) cm (range 9–20 cm). Using discriminant analysis, a sternomental distance of 13.5 cm or less was calculated as the most accurate cut-off point for discriminating between difficult (grades III and IV) and easy laryngoscopy (grades I and II). There was a significant difference (P=0.0013) between mean sternomental distance for laryngoscopy grades I and II (14.3 (1.49) cm) and laryngoscopy grades III and IV (13.17 (1.54) cm). Sensitivity, specificity, positive and negative predictive values for the cut-off point of 13.5 cm and for each measured sternomental distance are shown in table 3. Figure 1 shows the ROC curve for the various sternomental distances. Figure 2 shows the relative risks and 95% confidence intervals for the probability of a grade III or IV laryngoscopy compared with grade I or II at specific cut-off points. For example, at a sternomental distance of 12 cm, experiencing a grade III or IV laryngoscopy was 5.6 times (95% CI 2–14) more likely than a

<16.0	50	100	7.9	3.7	100

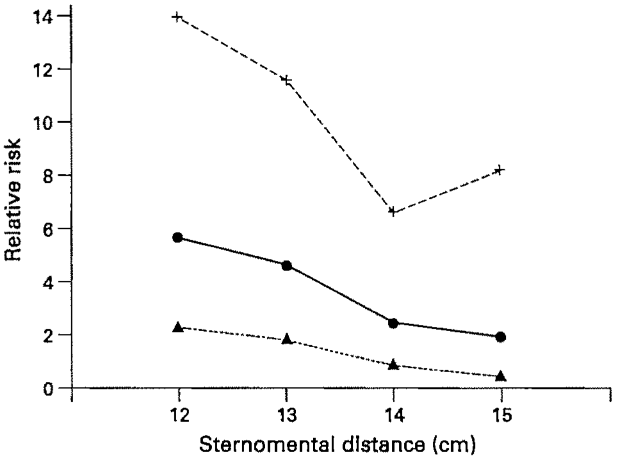

Figure 2 Relative risk (95% CI) of experiencing a grade III or IV laryngoscopy compared with a grade I or II view at laryngoscopy for different sternomental distances.

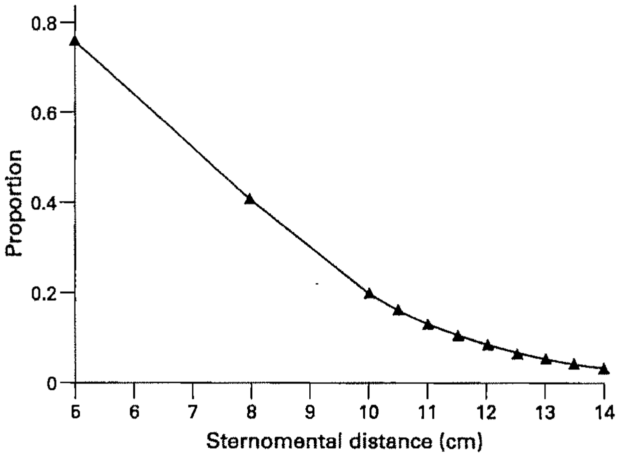

Figure 3 Probability of finding a grade III or IV view at laryngoscopy for each sternomental distance calculated when the prevalence of such grades is 3.5%. Where the prevalence is found to be different, a new probability curve can be calculated using the logistic regression equation logit(P)=−3.738+0.5143×D, where D=sternomental distance and P=probability of grade III or IV laryngoscopy.

grade I or II. Figure 3 shows the probability of experiencing a grade III or IV laryngoscopy for each sternomental distance.

Eighteen (3.5%) of the 523 patients had a grade III or IV view at laryngoscopy. Seventeen of the 18 patients had a grade III while one had a grade IV. Of the 17 who had a grade III view at laryngoscopy, the trachea in 13 was intubated without difficulty with or without the aid of a gum elastic bougie. Of the remaining four, two had the tube passed blindly without the use of a gum elastic bougie while in the other two a laryngeal mask was used because of the difficulty in passing the tracheal tube, even with the aid of a gum elastic bougie. In the grade IV patient, the tube went into the oesophagus after a blinded attempt at intubation. On recognition of oesophageal placement the tube was removed immediately. A laryngeal mask was then inserted but difficulty was experienced with ventilation. The patient was awakened and Caesarean section subsequently completed under spinal anaesthesia.

Discussion

Head extension is thought to be an important factor in determining the ease or difficulty of tracheal intubation[11]. However, several previous studies have made only subjective clinical assessments of reduced atlanto-occipital extension[3 6]. In the study of Bellhouse and Doré the anaesthetist viewed the patient from the side and estimated whether and to what extent there was any reduction in atlanto-occipital extension[3]. In the obstetric study of Rocke and colleagues, no objective assessment was made of reduced neck extension[6], rather, subjective assessment was made on whether or not the patient had a short neck. It was then assumed that the finding of a short neck would be associated with reduced ability to extend the head on the atlanto-occipital joint and thus impede adequate view of the larynx. The presence of a short neck was not only found in nearly 15% of cases but was highly significantly associated with subsequent difficulty at tracheal intubation.

The predictive value of a short neck is somewhat controversial[3]. Bellhouse and Doré questioned the relationship between length of the upper neck and difficult intubation. In their study comparing an easy with a difficult intubation group, those with a longer neck were associated with greater difficulty. Yet paradoxically, within the difficult group the difficulty grade increased as the upper neck became shorter. They concluded that upper neck length, measured radiographically as the length of the four upper cervical vertebrae, should be regarded at best as controversial. Regardless, radiographic methods will always be impractical for routine screening and assessments of short neck remain subjective.

What is required is a quick, simple test of head and neck mobility. Most recently Savva, in a largely non-obstetric population, found sternomental distance to be the most sensitive (82.4%) and specific (88.6%) determinant of difficult intubation of a group of five tests which included a modified Mallampati test, thyromental distance, forward protrusion of the mandible and interincisor gap[8]. A sternomental distance of 12.5 cm or less was found to be the best predictor whereas in this study a distance of 13.5 cm provided the best balance between sensitivity and specificity. Reducing the sternomental distance cut-off point to 12.5 cm or less would result in greater specificity (87.3% *vs* 71.1%), a marginal improvement in the positive predictive value (11.1% *vs* 7.6%) but a significant reduction in sensitivity (44.4% *vs* 66.7%). In clinical practice this implies that by reducing the cut-off point to the same as Savva's criterion, a greater number of difficult laryngoscopies would be missed. The question arises as to which cut-off point from the two studies is the most appropriate. This can only be answered by future epidemiological studies on outcome where a defined test (e.g. sternomental distance at a specified distance) or series of tests are used and with outcome as either difficult laryngoscopy, intubation, or both.

In the study of Savva, four of 350 patients had laryngoscopy grades III or IV (1.14%) which is lower than the 3.5% prevalence in our study. Savva did not state how many of the four were obstetric patients and it is possible that increased weight gain associated with pregnancy resulted in a reduced ability to see the larynx[12]. This would be supported by our finding of an association between reduced laryngoscopic view and weight.

Comment should also be made on the one grade IV laryngoscopy case. Cormack and Lehane suggested that most of these cases would be associated with obvious anatomical pathology which would be easily recognized before operation[10]. Our grade IV case had no obvious pathology either before operation or at the postoperative examination. One possibility is that the laryngoscope blade was inserted too far thus completely obscuring the epiglottis and larynx. This may have been an explanation if the anaesthetist had been inexperienced but this was not the case. The most likely explanation is that the belief that all grade IV cases will have obvious pathology is erroneous.

There are several limitations to this study. First, we did not measure objectively other factors which could have contributed to the reduced laryngoscopic view. As stated, and because of the work of Savva showing sternomental distance to be the best predictor, we set out to determine if this could be reproduced in an obstetric population. A second criticism of the study is that we did not measure whether or not intubation was difficult. However, none of the grade I and II laryngoscopic views had a trachea which was difficult to intubate and most of the 16 grade III and IV cases were managed with ease with the aid of a bougie. Third, several different residents and faculties undertook laryngoscopy and it is possible that a uniform intubation position was not achieved. However, all staff participating in the study had a minimum of 2 yr experience of working solely in this obstetric hospital dealing with a case load where the primary method of provision of anaesthesia for Caesarean section is general anaesthesia. Some studies[13] have standardized the sniffing position by stabilizing the head in a commercial head and neck mould, but we felt that this would have been inappropriate for the obstetric patient.

It is clear that no simple test can be used alone. Measurement of sternomental distance will fail to predict some difficult laryngoscopies and also predict difficult laryngoscopy in a significant number of patients who have a trachea which is easy to intubate. This is not unexpected because on its own sternomental distance fails to take into account relative tongue and pharyngeal size, location of the larynx (mandibular space), overriding maxilla, enlarged incisors, decreased temporal–mandibular joint mobility and a narrow high arched palate. Nevertheless the results of this study confirm, albeit with a reduced predictability than Savva, that sternomental distance can be correlated with laryngoscopic view. We do not believe however that sternomental distance alone can be used as a predictive test, but our results suggest that such a measurement should be included as part of a series of preoperative airway examination tests which should also include view of the oropharynx and thyromental distance.

Respiratory mechanics after abdominal surgery measured with continuous analysis of pressure, flow and volume signals†

A. F. NIMMO AND G. B. DRUMMOND

Summary

We studied 10 patients during the first night after upper abdominal surgery to assess the effect of airway obstruction on chest wall mechanics, by recording nasal gas flow and carbon dioxide concentration, rib cage and abdominal dimensions, abdominal muscle activity, and oesophageal and gastric pressures. The mean duration of study of each subject was 5.8 h , and 5.2 h were analysed. The median proportion of time spent breathing with normal mechanics was 29% (interquartile values 0–57%). Abnormal abdominal mechanical events were common and associated with airway obstruction (P<0.001). Two common patterns of abnormal pressure and movement were found. In the first, abdominal pressure decreased at the onset of inspiration and there was a phase lag in abdominal movement. The incidence was 33 (14–50) %. In the second pattern, abdominal pressure decreased and in addition the abdominal wall moved inwards at the onset of inspiration. This occurred for 34 (0–52)% of the time. Both patterns were associated with evidence of increased activation of the abdominal muscles during expiration, changing the relationship of abdominal and pleural pressure changes and chest wall movements. Such changes have been interpreted previously as evidence of diaphragm dysfunction. (*Br. J. Anaesth.* 1996;**77**:317–326)

Key words

Airway, obstruction. Analgesia, postoperative. Complications, respiratory. Surgery, abdominal. Muscle respiratory.

Abdominal surgery influences respiratory pattern, but effects on respiratory muscles are not well described. Measurements of respiratory movements and pressures have led some workers to conclude that the activity of the diaphragm is impaired[1 2]. After surgery, i.v. or extradural administration of opioids can cause episodic airway obstruction and result in periods of hypoxaemia[3 4].

We investigated systematically how analgesia, airway obstruction and hypoxia may be related. To select simple but appropriate methods of measurement of these events, we examined a limited number of patients on the first night after operation. We intend in subsequent studies to measure fewer variables, which could be performed more easily, yet still be interpreted correctly. We also examined the possibility of "diaphragmatic inhibition", which has been inferred in previous studies from the relationship between pleural and abdominal pressure changes.

Patients and methods

THEORY OF ANALYSIS

We used a graphical analysis of respiratory pressures and dimensions. Chest wall movement (fig. 1D) is considered to be in two compartments, rib cage and abdomen, which can move independently to change chest wall and lung volumes, although commonly both expand simultaneously on inspiration and return along the same trajectory on expiration. Action of other muscles, such as the abdominal wall muscles, can separate the inspiratory and expiratory lines. A small amount of asynchrony is normal[5]. Paradoxical motion can occur, despite inspiratory flow, when one compartment moves inward but not sufficiently to negate the outward motion of the other. With no flow, movement is constrained to the "isovolume" line, where the volume changes of the rib cage and abdomen are equal and opposite. Often, outward motion of the abdomen on inspiration is considered to indicate the action of the diaphragm, and outward rib cage motion to indicate the action of the intercostal and other inspiratory rib cage muscles. However, the diaphragm contributes considerably to rib cage expansion. Its costal fibres elevate the rib margin[6]. If the abdominal wall is firm, then the relatively incompressible abdominal contents form a "fulcrum" that allows contraction of the diaphragm to increase abdominal pressure, which expands the lower rib cage through the "zone of apposition" where the diaphragmatic and rib cage pleural surfaces are in contact[7]. The relative amount of rib cage and abdominal displacement caused by diaphragm action depends on the relative compliances of these two compartments[8], and also on the action of other muscle groups at the same time[9]. If the abdominal wall is tense, then the diaphragm mainly expands the rib cage. Observing the motion of the rib cage and abdomen (such as RC/AB ratio) is

†Presented in part at the Anaesthetic Research Society, London Meeting, November 11, 1994 (*British Journal of Anaesthesia* 1995; 74: 486P).

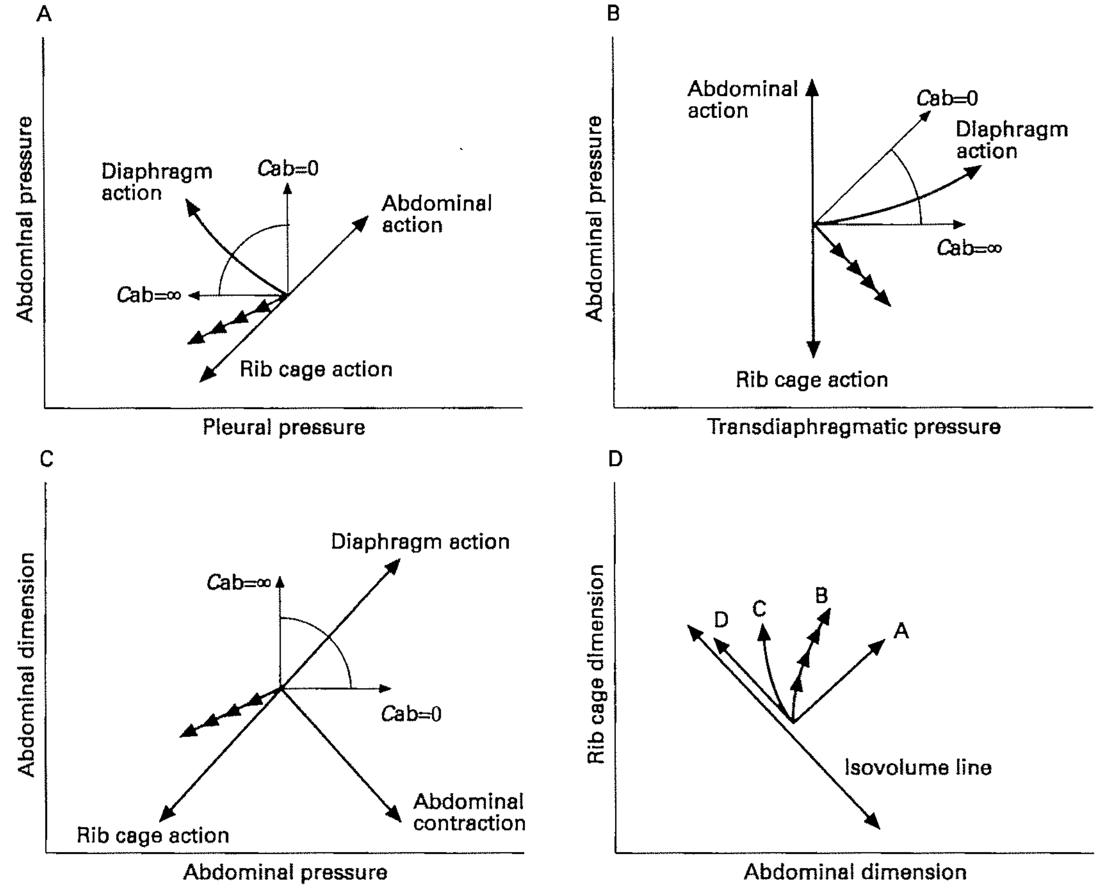

Figure 1 Rib cage and abdominal pressures and dimensions. A: Abdominal *vs* pleural pressure. Normal active inspiration is associated with a decrease in pleural pressure; when the diaphragm contracts, abdominal pressure increases. The direction of the plot depends on the relative compliances of the rib cage and abdomen, and the activities of other muscles, but the direction associated with diaphragm action alone is constrained between the theoretical lines shown for infinite and zero abdominal compliances. Inspiration with the rib cage muscles alone is in the direction "rib cage action" and expiration with the abdominal muscles in the opposite direction (abdominal action). B: Abdominal *vs* transdiaphragmatic pressure (*P*di = *P*ga−*P*pl). C: Abdominal dimension *vs* abdominal pressure. The direction of movement associated with the sole action of rib cage inspiratory muscles, abdominal expiratory muscles and the diaphragm are shown. The direction of the latter depends on abdominal compliance but is constrained within the sector shown. D: Rib cage *vs* abdominal dimensions (arbitrary units). Different trajectories of inspiration are shown: A=normal inspiration; B=inspiration when the abdomen is relatively tense, and most of the motion occurs by the rib cage; C=inspiration with paradoxical inward motion of the abdomen; and D=an isovolume manoeuvre where the increase in rib cage volume is the same as the decrease in abdominal volume. In each quadrant, the line with multiple arrowheads indicates the direction of movement during inspiration where there is predominant contribution from rib cage muscles.

not enough to allow changes in activity of the diaphragm to be inferred unless the compliances of the two compartments remain constant.

ANALYSIS OF PRESSURES

Measurements of abdominal and pleural pressures (conveniently plotted graphically in fig. 1) allow better discrimination of respiratory muscle action.

Action of the rib cage muscles

Inspiratory action of rib cage muscles (such as external intercostals and scalenes) expands the rib cage and decreases pleural pressure *P*pl. If the diaphragm is inactive, transdiaphragmatic pressure is zero (*P*di=*P*ab − *P*pl). Consequently, as pleural pressure decreases, abdominal pressure decreases equally. The diaphragm and abdominal contents are drawn cranially, and the abdominal wall moves inwards.

Abdominal expiratory muscle action

Expiratory muscle action alone has the opposite effect on *P*ab and *P*pl. Inward motion of the abdominal wall increases abdominal pressure, displaces the diaphragm cranially, increases pleural pressure and causes expiration. Inspiration can then occur if the abdominal muscles subsequently relax and result in descent of the diaphragm. This action is difficult to distinguish from rib cage activation.

Diaphragm action

Contraction of the diaphragm generates a transdiaphragmatic pressure. The relative changes in pleural pressure and abdominal pressure during inspiration depend on the relative compliances of the rib cage and abdomen (fig. 1A). If the compliance of the abdomen were infinite, then pressure change would occur only by a decrease in pleural pressure. In practice, transdiaphragmatic pressure cannot be generated without a corresponding increase in abdominal pressure. If the abdominal compartment has a very small compliance, abdominal pressure increases with a very small reduction in pleural pressure. It follows that the trajectory of the *P*ab against *P*pl plot caused by the diaphragm acting alone lies between these lines. If the diaphragm and rib cage muscles act together in inspiration, they can move the pressures in the segment between the line indicating zero abdominal compliance and the line indicating rib cage muscle action alone.

Diaphragm action may also be assessed with a plot of abdominal pressure *vs* transdiaphragmatic pressure (fig. 1B). Rib cage action decreases abdominal pressure with no change in *P*di and results in a vertically descending plot. Abdominal expiratory muscle action increases abdominal pressure with no change in *P*di (generating a plot opposite to that seen with rib cage inspiratory action, as has been noted in the *P*ab *vs P*pl diagram). Action of the diaphragm against a rigid abdomen results in equal increases in *P*ab and *P*di. If abdominal compliance is infinite, *P*di increases alone. Hence this plot differs from the previous (*P*ab *vs P*pl plot) because the sector for sole action of the diaphragm is smaller. However, as in the preceding diagram, any combination of diaphragm and rib cage action generates a plot in the sector between the line of zero abdominal compliance and the rib cage line. Although more information on the activity of chest wall muscles may be obtained from such plots than from measurements of compartmental movement, the relative contribution of each group of muscles cannot be distinguished exactly by this analysis: in particular, abdominal relaxation and rib cage activity appear similar.

ABDOMINAL DIMENSION/ABDOMINAL PRESSURE PLOT (FIG. 1C)

Action of inspiratory rib cage muscles and relaxation of abdominal muscles can be distinguished by plotting abdominal dimension *vs* abdominal pressure, as in a compliance graph. *Contraction of the expiratory muscles* generates inward movement of the abdominal wall and an increase in abdominal pressure. Inward wall movement can occur only if another part of the abdominal container is displaced, such as by cranial displacement of the diaphragm. If both the diaphragm and abdominal expiratory muscles contract at the same time, abdominal pressure increases with little decrease in abdominal dimension. *Inspiratory action of the rib cage muscles alone* moves the abdominal wall inwards and decreases abdominal pressure. *Diaphragm action* increases abdominal pressure and displaces the abdominal wall outward, and the slope of this plot indicates the compliance of the abdominal wall. Simultaneous inspection of this plot and the *P*ab *vs P*pl plot (fig. 1A) allows inspiratory events associated with abdominal relaxation to be distinguished from those caused by the inspiratory action of the rib cage.

AIRWAY OBSTRUCTION

If airway resistance is increased, muscle shortening is reduced and the tension developed by the muscles for a given degree of activation is increased. Pleural pressure decreases more, and gastric pressure increases less, as there is less displacement of the diaphragm. In addition, pleural pressure can no longer be used as an appropriate indicator of lung volume, as lower airway, alveolar and pleural pressures all decrease substantially during the inspiratory effort. In this condition, transpulmonary pressure (*P*ao − *P*pl, where *P*ao=pressure at the airway opening) differs considerably from the pressure difference between the alveolus and pleural space which is proportional to lung volume.

We developed the hypothesis that prevention of muscle shortening could increase neural activation by reflex mechanisms, notably the stretch reflex mediated by muscle spindles. Rib cage muscles have a clear postural role and are richly supplied with muscle spindles[10]. Impedance of inspiration may result in their reflex activation, and an increased contribution to inspiratory force. This will alter the trajectories of the *P*ab *vs P*pl, *P*ab *vs P*di and abdominal volume *vs* pressure plots in the directions shown in figure 1.

PROCEDURE

After obtaining approval from the regional Ethics Committee and written informed consent, we studied patients aged 40 yr or more, undergoing major abdominal surgery that would involve an incision at least partly above the umbilicus, and who would be cared for after operation in the surgical high dependency unit. Exclusion criteria were severe cardiac, respiratory or renal disease, or a body weight more than 130% of that predicted on the basis of sex, age and height. For postoperative analgesia, six patients received patient-controlled analgesia (PCA) with either morphine or diamorphine i.v., and four received a continuous thoracic extradural infusion of 0.125% bupivacaine containing diamorphine 0.033 mg ml^{-1} at 10 ml h^{-1}.

A nasogastric tube with an integral oesophageal balloon (Mallinkrodt) was modified by attaching a gastric balloon to the tube tip. This was inserted via a nostril during anaesthesia, and placed to allow estimation of oesophageal and gastric pressures (*P*oes and *P*ga) using differential transducers (Furness FC10). *P*oes and *P*ga are used as measures of *P*pl and *P*ab, respectively. Transdiaphragmatic pressure (*P*di) was calculated as (*P*ga − *P*oes). The gas volume in each balloon was checked regularly and adjusted. Pressure calibration was against a water manometer.

Patients received oxygen 2 litre min^{-1} via nasal cannulae after operation. Pressure fluctuations in the nasal cannulae were measured to allow estimation of gas flow at the nose[11]. A narrow sampling tube was inserted through the centre of one cannula to allow sampling of carbon dioxide concentration for measurement by an infrared capnometer (Engstrom Eliza). Rib cage and abdominal dimensions were measured by inductance bands placed around the rib cage immediately below the axillae and around the abdomen at the level of the umbilicus, and avoiding the rib margins if possible. Disposable ECG electrodes were attached in the right upper quadrant of the abdomen to measure abdominal muscle EMG[12]. An Ohmeda 3700 pulse oximeter with a finger probe was used to record oxygenation continuously. The signals were recorded using a high speed analogue to digital converter (RTM8, Digitimer Ltd) which played into a domestic video recorder and allowed up to 8 h of continuous recording, sampling at a rate of 11 kHz per channel. The monitoring apparatus was set up in the evening after operation, and recordings made over the first night. One investigator (A.F.N.) remained with the patient overnight, supervising the quality of the recorded signals. Occasional adjustments were necessary, particularly to the gastric and oesophageal balloons, and the nasal flow measurement system.

Further analysis involved playing back the videotaped record onto an eight-channel chart recorder (Graphtec WR3600). These records were then analysed by an observer who was unaware of the clinical circumstance of the patient. Each record was divided into segments of 5 min each, and each segment was classified according to preset criteria. First, the segment was classified as analysable, depending on the satisfactory recording of all the signals. Next, the presence or absence of central apnoea or hypopnoea, or obstructive apnoea or hypopnoea, was determined for each analysable segment. Central apnoea was determined by the absence of nasal flow, no changes in oesophageal pressure and no change in rib cage or abdomen dimension for more than 15 s. Central hypopnoea was defined by a reduction in amplitude of gas flow at the nose with a reduction in oesophageal pressure change. Obstructive hypopnoea was defined by a decrease in gas flow at the nose, associated with an increase in oesophageal pressure changes, and obstructive apnoea as no gas flow and increased oesophageal pressure changes.

The records were then re-analysed for the presence of mouth breathing, which was defined as continued chest wall movements, no change in oesophageal pressure swings and loss of nasal flow and carbon dioxide signals. This definition implies that the patient was breathing through the mouth and not through the nose: however at other times the patient may have been breathing through both the nose and mouth.

Finally, each segment was inspected for the presence of abnormalities of chest wall mechanics which were classified according to table 1. An inspiratory attempt was recognized from a decrease in oesophageal pressure. Because the exact time of *onset* of inspiration on the pressure trace was often indistinct because of cardiac oscillations, the times of *onset and end of inspiration* were obtained from the tracing of rib cage dimension. In one patient whose rib cage dimension sometimes decreased on inspiration, oesophageal pressure was used to time inspiration. EMG signals were not analysed formally by integration but were used to assess the presence and pattern of abdominal muscle activity.

Statistical analysis of the association between abnormalities present in each time segment of each subject was performed using a log-linear model with the P4F program from the BMDP package (BMDP statistical software, 1988). Partial association was sought between pairs of the following categorical variables, after allowing for interaction between the other two variables: airway patency (i.e. airway clear or airway obstructed); chest wall mechanics (i.e. normal or abnormal chest wall and pressure changes); route of respiration (i.e. nose or mouth breathing); subject number (i.e. each patient).

Table 1 Summary of changes at the start of inspiration for different breathing patterns

	Change in gastric pressure	Movement of abdomen	Movement of rib cage
Normal	Increase	Outward	Outward
Gastric pressure paradox	Decrease	Outward	Outward
Abdominal movement paradox	Decrease	Inward	Outward
Ric cage paradox	Increase	Outward	Inward

To investigate the patterns of changes in the recorded variables, values for each patient were re-digitized from the replayed analogue signals using a commercial software package (Cardas, version 2.07, Oxcams Ltd, Oxford) at 20 Hz and plotted at 10 Hz using Fig P for windows version 1 (Biosoft, Cambridge), with a standard plot as in figures 3–5.

Results

Patient details are shown in table 2. Most patients were aged more than 60 yr and none was overweight. Results are given as median (quartile values). The number of 5-min periods of recording for each patient was 71 (68–72) and of these, 7 (5–10) could not be analysed. There was no evidence of airway obstruction in only 10 (3–22) of the periods analysed, and no abnormality of chest wall mechanics in 14 (0–36). Mouth breathing varied considerably between patients, being present in a median of 10 (1–38) periods per patient. The frequency of these abnormalities for each patient is given in table 3. There was no clear difference between patients using PCA and those receiving extradural analgesia. Airway obstruction and abnormal chest wall mechanics were related significantly ($P<0.0001$), but the relationship between mouth breathing and abnormal mechanics was not significant ($0.05<P<0.1$).

Table 3 also gives the relative distribution of the abnormalities of chest wall mechanics. There was no clear difference between the two types of analgesia. Both gastric pressure paradox and abdominal movement paradox were frequent (33 (14–50) % and 34 (0–52) % of the time, respectively). We noted that when these patterns were present, there was increased abdominal muscle activity on the EMG record. Ventilatory frequency over the study varied considerably between patients, with a median of 13.5 (9.5, 14.5) bpm. For each patient, ventilatory frequency also varied considerably within the study, increasing with arousal. There were no episodes of central apnoea. Determination of the incidence of central hypopnoea was difficult. We defined central hypopnoea as a reduction in both nasal gas flow and oesophageal pressure change during inspiration, that is a decrease in both tidal volume and effort. However, such changes were universal during recovery from an episode of airway obstruction, associated with a presumable decline in hypercapnic stimulation. A decrease in both nasal gas flow and oesophageal pressure change was not evident at other times, and we concluded that "central hypopnoea" was not present in these patients.

PATTERN OF CHANGE IN PRESSURE AND MOTION

Most breathing was either normal, had paradox of gastric pressure or had paradox of both gastric pressure and abdominal movement. An example is given in figure 2, showing progression from a normal pattern, to paradox of gastric pressure, then abdomi-

Table 2 Details of patients. RUQ = Right upper quadrant of the abdomen. Opioid doses are given as milligrams of morphine, assuming half the potency of diamorphine. Intraoperative doses include those given on recovery from anaesthesia. All extradural opioids were diamorphine. Intraoperative doses given to patients with extradurals are divided into extradural (e) and i.v. Pre-study amount = Amount given before the study started.

nal movement paradox, followed by resumption of normal breathing.

Representative plots of breaths of each type, obtained from the records of another patient, from a period of 30 min, are shown in figures 3–5.

Normal breath (fig. 3)

Plots of *P*ga *vs P*oes and *P*ga *vs P*di showed "looping". At the start of inspiration, *P*oes decreased promptly. The direction of the early inspiratory plot was only just in the "diaphragm action" sector. In the second part of the inspiration, gastric pressure increased and remained increased during the first part of expiration. The plot of abdominal dimension against gastric pressure showed that in the first half of inspiration there was little increase in either gastric pressure or abdominal volume. In the second half of inspiration, abdominal dimension increased smoothly as gastric pressure increased. The plot of rib cage and abdominal dimensions showed that early in inspiration the relative proportion of rib cage dimension increase was greater than that of the abdomen, whereas during expiration both dimensions decreased progressively and in the same proportion, so clockwise "looping" is seen. This pattern was seen in all patients.

The changes in this type of breathing can be summarized as oesophageal pressure and rib cage dimension changing in advance of abdominal dimension, with gastric pressure and abdominal dimension changing in phase in the later part of inspiration. In expiration, gastric pressure and transdiaphragmatic pressure decreased, and oesophageal pressure increased. The plot of abdominal dimension against gastric pressure decreased along a plot that was the reverse of inspiration.

Gastric pressure paradox (fig. 4)

Figure 4 shows a breath sampled in the same patient, approximately 30 s before the example in figure 3. Gastric pressure decreased early in inspiration. All patients showed this pattern of change at some time during the study. The *P*ga *vs P*oes and *P*ga *vs P*di plots showed an initial downward descent, and then an increase in gastric pressure in the second part of inspiration. The abdominal dimension/gastric pressure plot showed a deflection in a horizontal direction (i.e. no change in abdominal dimension during early inspiration) before both dimensions increased in the second half of inspiration. This pattern of abdominal dimension/*P*ga plot was most common, but in two patients an increase in abdominal dimension occurred as gastric pressure decreased. On the dimension plot, outward rib cage motion started with no initial change in abdominal dimension. In the second half of inspiration, and in expiration, the shape of this plot remained similar to that seen in a normal breath.

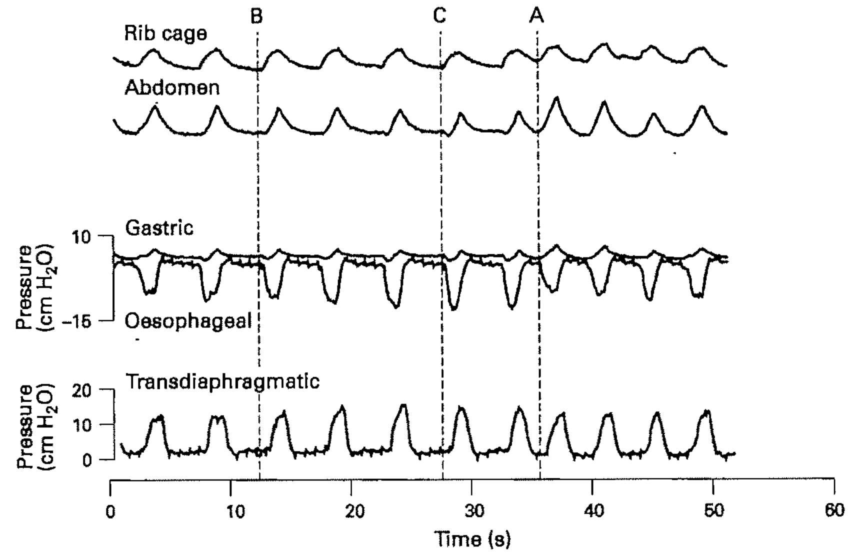

Figure 2 Chest wall dimensions, oesophageal and gastric pressures, and derived diaphragmatic pressure in one patient, illustrating the different types of abnormality. At A, a normal breath with increases in rib cage and abdominal dimension, and gastric pressure, at the start of inspiration; at B, gastric pressure decreases at the onset of inspiration; at C, both gastric pressure and abdominal dimension decrease at the start of inspiration.

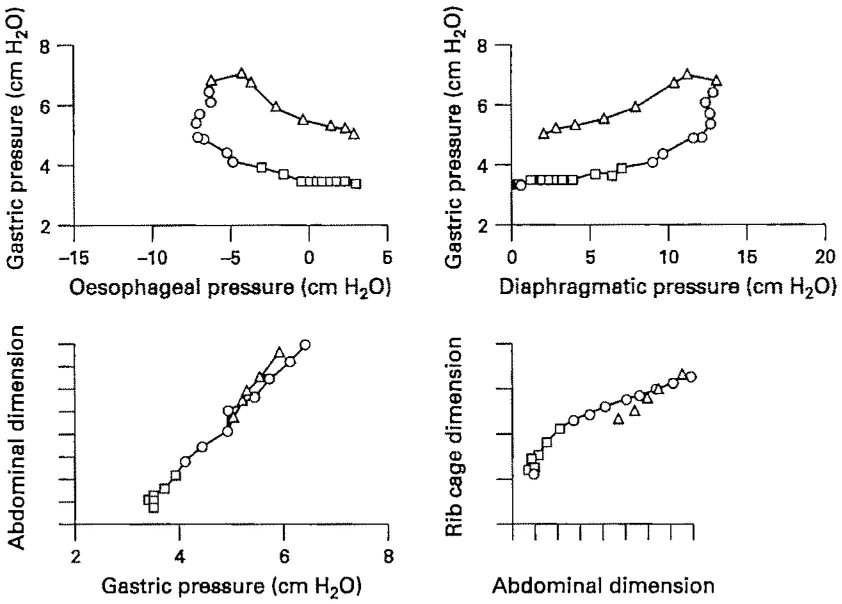

Figure 3 A single breath showing a normal pattern of breathing. The first half of inspiration is shown with the symbols (□) the second half with the symbols (○) and the subsequent early part of expiration with the symbol (△). Rib cage and abdominal dimensions are in arbitrary units; abdominal dimension is used with a common scale on the two plots. (The final part of expiration has been omitted for clarity, see text for further discussion.)

Abdominal movement paradox (fig. 5)

Gastric pressure, oesophageal pressure and abdominal dimension decreased during the first part of inspiration. On the plot of abdominal dimension and gastric pressure, gastric pressure and abdominal dimension decreased in concert at the start of inspiration but then increased in the second half of inspiration. A particular feature of this type of breathing was that during expiration, abdominal dimension decreased as gastric pressure either remained unchanged or increased. This is shown clearly in the example, and was seen in all subjects. As expected, rib cage dimension increased but abdominal dimension decreased at the start of inspiration, but again in late inspiration both dimensions increased together.

In several subjects, rapid and frequent changes between these breathing patterns were noted, whereas in other patients more stable patterns of breathing, particularly that of gastric pressure paradox, were noted. Often airway obstruction became progressively more severe and ended with apparent arousal and restoration of a temporarily normal breathing pattern.

All patients received oxygen 2 litre min^{-1} from a nasal cannula. Despite airway obstruction, oxygen saturation did not decrease to less than 90% in any patient. Occasionally the oxygen saturation display was less than 90%, but in each of these events, the observer could see both the patient and the plethysmographic waveform displayed by the oximeter, and judged the low saturation value artefactual, usually caused by patient movement.

Discussion

We have described the patterns of respiratory mechanics that occur after major abdominal surgery

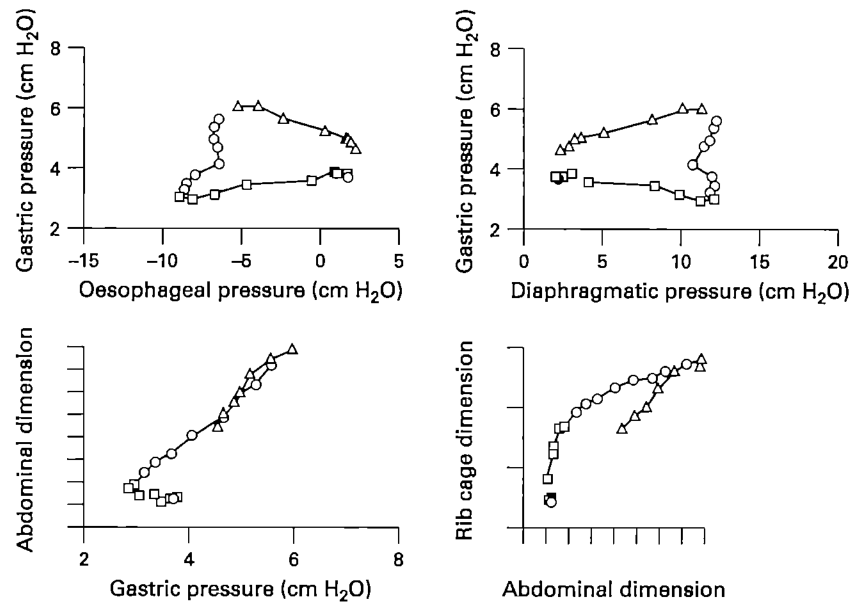

Figure 4 A single breath, from the same patient as in figure 4, showing a reduction in gastric pressure at the onset of inspiration. Symbols as in figure 3. Rib cage and abdominal dimensions are in arbitrary units. Note the increased "looping" in the gastric pressure *vs* oesophageal pressure and gastric pressure *vs* diaphragmatic pressure plots during the first part of inspiration, indicating a phase shift, with pressure in the oesophagus "leading" gastric pressure.

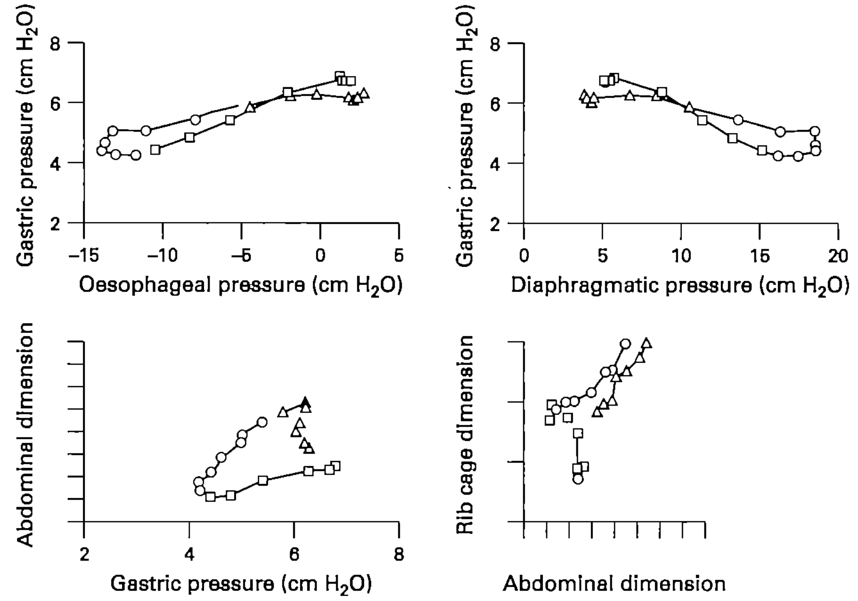

Figure 5 An example of a single breath, from the same patient as in figure 4, showing a reduction in abdominal dimension at the onset of inspiration. Symbols as in figure 3. Rib cage and abdominal dimensions are in arbitrary units. Note the greater changes in oesophageal and transdiaphragmatic pressure. These changes suggest increased tension in the inspiratory muscles. The decrease in gastric pressure at the onset of inspiratory attempt, synchronous with the decrease in abdominal dimension, indicates an increased contribution from rib cage muscles.

in association with breathing and breathing disturbances. These patterns proved remarkably consistent, although the relative changes were complex. Statistical analysis of the changes was categorical because several factors prevented a more quantitative approach.

The oesophageal balloon method is not of great value for estimating the absolute value of pleural pressures in supine subjects, particularly when lung volume is small, although pressure changes can be measured satisfactorily[13]. In our subjects, abdominal muscle activity was frequently present to some degree, so the absolute values of gastric pressure would be affected. However, we believe that within-breath changes can be used descriptively, as we have done in the example shown, and that breaths a few minutes apart (as in figs 3–5) can be compared usefully.

Measurement of chest wall motion using inductance bands is a simple and non-invasive method, but is often difficult in recumbent patients[14 15] or after operation[16]. Our patients were always supervised closely to ensure that the bands remained in about the same place, but changes in position disturbed the signal for some time and was the most common reason for an uninterpretable trace. There are several alternative methods for calibration of the inductance band device, but only the original isovolume manoeuvre is sufficiently robust statistically to properly partition abdominal and rib cage volume contributions[17]. Repeated calibration of the bands under the conditions of this study was impossible, and we only used these signals qualitatively. For example, a simultaneous reduction in the changes in oesophageal pressure and rib cage dimension was interpreted as a decrease in respiratory drive. Such changes were noted cyclically in some patients during recovery from an episode of obstruction.

We used nasal pressure signals similarly to provide a breath-by-breath indication of flow. Clear changes were seen in association with obstruction, followed by arousal, with transient increases in flow and breathing movements. EMG signals can be quantified by rectification and integration, but we were unsure of the stability of the recording system over several hours. The signals were used to indicate the phase and pattern of external oblique activity.

The patterns of motion observed are worthy of comment, and each variable studied will be considered in turn. Pressures related to elastic and resistance components can be distinguished by their relationship to flow and volume change. For example, the flow-related component of the oesophageal pressure change is more than doubled after sedation with midazolam[18] because airway resistance is increased. Oesophageal pressure change is greater, for the same degree of neural activation of the inspiratory muscles, if inspiration is impeded. This is partly because the muscles shorten less and more pressure is generated. The extreme example of this is occluded inspiration where the muscles contract but cannot shorten, other than to distort the chest wall, and oesophageal pressure decreases considerably more than during a normal breath. If airway resistance is increased, but flow is *not* reduced, then the inspiratory muscle activity must have increased. Transpulmonary pressure during inspiration, associated with that flow, is greater because of the increased resistance. We infer that airway obstruction is responsible for the increased change in oesophageal pressure early in inspiration that could be seen when the abdominal wall moved *inward* during inspiration, and this inference was supported by the statistical association between episodes of airway obstruction and abnormal chest wall mechanics.

In a normal breath, gastric pressure and abdominal dimension increase and decrease together, suggesting that abdominal motion is the result of diaphragm action, and that the compliance of the anterior abdominal wall does not change during the respiratory cycle.

On the other hand, abdominal wall compliance clearly *does* alter when gastric pressure decreases at the start of inspiration (fig. 4). At the same time, rib cage dimension increases and oesophageal pressure decreases rapidly. Such changes could be caused by the inspiratory action of the rib cage. They could equally well be the result of relaxation of the abdominal muscles, if these muscles have acted to decrease the dimensions of the lower rib cage, or possibly caused by both of these actions. These alternatives can be distinguished partly by considering the abdominal dimension/gastric pressure plot, so that the inspiratory action of rib cage muscles and relaxation of the abdominal expiratory muscles generate movement of the plotted values in different directions. The slope of the plot depends on the compliance of the abdomen. Abdominal compliance is small if the abdominal muscles and diaphragm are contracting at the same time, whereas it is greater if the inspiratory rib cage muscles are active alone, as the abdominal contents are drawn passively in a cranial direction as pleural pressure is reduced. In this study, abdominal pressure decreased with little change in abdominal dimension, so the abdomen or diaphragm was relaxing. Previous observations suggest that large changes in gastric pressure, particularly during expiration, can be related directly to abdominal muscle activity[19 20].

When both gastric pressure and abdominal volume decrease together, there must be a dominant effect of the rib cage inspiratory muscles. Even when the abdomen moves paradoxically on inspiration, transdiaphragmatic pressure still increases (fig. 5), indicating that the diaphragm is active, and that it is contracting against an increased respiratory impedance. Indeed, pressure changes tended to be greater when respiration was impeded. However, this action does not displace the abdominal contents because gastric pressure shows no increase. In such conditions, assessment of "dysfunction" using changes in transdiaphragmatic and gastric pressure is impossible. We had no index of diaphragmatic activation, as could be provided by electromyography. However, the commonly used index of contractility, the ratio of EMG to *P*di, is altered by both posture and the degree of abdominal muscle activity[21], and therefore this would not have been of great value. Other workers have found that maximum diaphragmatic electromyographic activity is reduced after abdominal surgery but this appears to be in proportion to the reduction in tidal volume[22]. Contractility appears unaffected[23]. Similarly, extradural analgesia was noted to restore both electrical activity and tidal volume by approximately similar amounts[24]. Paradoxical chest wall movements similar to those we have described have been noted in obese patients with sleep apnoea[25] and patients with airway obstruction after surgery[26].

We suggest that these abnormal patterns of gastric pressure and abdominal dimension indicate activity of the inspiratory rib cage muscles and abdominal expiratory muscles. Airway resistance probably activates the intercostal muscles because of the stretch reflex. Intercostal muscles have many muscle spindles[10] and have a clear reflex response to imposed loads[27 28]. In contrast, the diaphragm has few spindles and no clearly defined reflex response to loads, other than via vagal reflexes[29]. Rib cage movement is thus greater in early inspiration and this feature can be seen to a lesser extent even in "normal breathing" after operation (fig. 3). The decrease in gastric pressure was similar but not identical to that seen in unilateral diaphragm paralysis[30] or in the horse[31] when the abdominal muscles are used to assist expiration. EMG assessment of the relative timing and activation of the diaphragm and intercostal muscle activity would be helpful to examine the possible reflex augmentation of intercostal activity in early inspiration.

Previous workers have used the relationship between gastric and oesophageal pressure changes to assess the relative contribution of the diaphragm[1 2]. This approach is generally valid if *only* the diaphragm or inspiratory rib cage muscles, or both, are active; in the present situation, there may be differences in the *timing* of activity of these muscles, the magnitude of their reflex activation by increased airway resistance may differ and, in addition, the abdominal muscles are active in expiration.

Opioid administration may enhance rib cage stiffness. Patients in this study received only moderate quantities of opioid (table 2). Extradural analgesia had no clear influence on abnormal chest wall mechanics.

Opioid administration may also influence the observed changes by provoking airway obstruction, particularly during sleep. Previous observers found that episodes of airway obstruction were associated with episodes of desaturation. Catley and colleagues[3] found that hypoxaemic episodes occurred during sleep and were associated with obstructive apnoea and opioid analgesia. However, their identification of episodes of airway obstruction depended entirely on the quantitative use of the inductance band method, which is unlikely to remain accurate for long periods of time. Although these workers have illustrated paradoxical changes in chest wall dimensions similar to those in this study[26], such movements have been incompletely investigated and described. We found that outward rib cage motion was almost completely preserved during airway obstruction and conclude that although this movement does not indicate abnormalities of breathing in patients after operation, it provides a reliable indication of inspiratory effort. Measurement of gas flow at the nose in addition to rib cage movement allows airway obstruction to be recognized. The combined measurement of rib cage movement and gas flow at the nose could provide an indication of airway obstruction with minimal disturbance to the patient. An episode of obstruction would be recognized reliably by outward movement of the rib cage (showing an inspiratory effort) with absence of gas flow at the nose.

Acknowledgements

This research was supported by a grant from the Scottish Hospital Endowments Research Trust, by W. J. Underwood's testamentary trust, and a grant from the Association of Anaesthetists of Great Britain and Ireland. We thank Professor J. A. W. Wildsmith who was instrumental in obtaining the major funding for this study and for his advice and encouragement. Dr R. J. Prescott of the Department of Public Health Sciences of Edinburgh University provided statistical advice and assistance.

Thoracic impedance used for measuring chest wall movement in postoperative patients

G. B. DRUMMOND, A. F. NIMMO AND R. A. ELTON

Summary

Thoracic impedance (TTI) and rib cage inductance band (IB) signals were measured in 10 patients during the first night after abdominal surgery, and compared by successive correlation of the change in each signal. Poor matching of the signals occurred, on average, for 94 min either because of movement or differences in the waveform. There were frequent episodes of transient poor correlation, generally associated with transient respiratory disturbance, predominantly airway obstruction (58%). Thoracic impedance measurements are simpler than inductance band methods for detecting rib cage movement and may be useful for large studies of respiratory abnormalities in patients after operation. (*Br. J. Anaesth.* 1996;**77**:327–332)

Key words

Ventilation, postoperative. Ventilation, rib cage. Measurement techniques, thoracic impedance.

Breathing abnormalities, including episodes of central and obstructive apnoea[1] and disturbed chest wall movements[2], are frequent after major surgery. Central and obstructive apnoea can be distinguished by measures of both chest wall movement and airway flow. We know of no studies of patients after operation in which the reliability of such measurements has been assessed, and only one in which the number of artefacts has been reported[3]. This type of information is particularly important if automated methods of data analysis are contemplated.

Chest wall movement is commonly attributed to contributions from the rib cage and abdomen, and the motion of these two "compartments" can be used to predict respired volume[4]. After operation, abdominal movements are frequently abnormal or even paradoxical[2], whereas rib cage movement remains in phase with respiratory effort and better indicates inspiratory activity. Chest wall movement is measured most often by means of inductance bands[5] which detect changes in the self-inductance of a coil placed round the chest wall in an extensible band: changes in the signal are thought to represent changes in area, although this may not be correct[6]. Circumferential length sensors have also been used[7–9]. Such devices can estimate tidal volume but are affected by body motion[10], posture[11], sleep[12] and airway obstruction[13], and the bands can be inconvenient. We have re-examined the value of transthoracic impedance (TTI) to indicate rib cage movement[14]. The method is simpler and less obtrusive, using adhesive electrodes to measure the voltage generated across the chest surfaces by the presence of a small constant current, usually applied via the sensor electrodes themselves. Previous studies attempted to relate TTI directly to respired volume, but this is now recognized as being inappropriate[15 16]. TTI has been compared previously with inductance bands[17 18] but not in patients after surgery, so the suitability of the two methods for this is not known. We have studied how well TTI and rib cage inductance signals compare, to give a qualitative index of rib cage movement, how reliable these methods are and the reasons for discrepancies between the signals.

Patients and methods

Patients gave informed written consent and local Ethics Committee approval was granted. We studied 10 patients after major abdominal surgery over the first night after operation while they were in a surgical high dependency unit. Criteria for admission to the study were an abdominal incision extending above the umbilicus and age more than 40 yr. Patients were excluded if they were chronically hypercapnic or had a body weight more than 130% of that expected on the basis of sex, age and height. Analgesia was provided with either a thoracic extradural infusion or i.v. patient-controlled injections of morphine.

Transthoracic impedance was measured with a device constructed in the Department of Medical Physics and Medical Engineering. It gave a constant current of 1.5 mA rms, frequency 70 kHz and was connected to the chest wall via two Medicotest ECG electrodes, one on the right mid-axillary line at a level corresponding to the V6 ECG electrode position and the other medial to the top of the left anterior axillary line. Earlier studies showed these positions gave more reliable waveforms than when electrodes were placed in both mid-axillary lines. The amplifier output was filtered (bandwidth 0.01–1.4 Hz, −6 dB octave^{-1}).

Rib cage movement was measured with an inductance band placed round the rib cage immediately below the axillae. It used an alternating current of 100 kHz and self-inductance was measured with another device made by the Department of Medical

Table 1 Incidence and duration of episodes of poor correlation caused by patient movement and lack of correspondence between the two waveforms

		Patient movement		Poor waveform correspondence (min)		
Patient No	Total time measured (min)	No. of episodes	Total duration of episode (min)	TTI abnormal	Inductance abnormal	Both abnormal
1	358	3	10	0	0	0
2	357	1	3	0	0	0
3	356	2	5	185	0	0
4	358	2	14	58	0	19
5	357	1	2	141	0	13
6	357	4	18	0	114	0
7	356	14	46	33	0	0
8	357	0	0	129	0	0
9	357	2	4	0	0	0
10	353	4	7	0	0	133

Physics and Medical Engineering. The amplifier output was filtered (bandwidth 0.03–16 Hz, −6 dB octave^{-1}). Another band was placed around the abdomen at the level of the umbilicus, but only the signal from the rib cage inductance band was used for comparison with the TTI signal.

Gas flow at the nose was measured from pressure fluctuations in a nasal oxygen cannula system[19] measured using a differential transducer (Furness FC10, Bexhill, Kent). Signals were sampled continuously every 88 μs with an AD converter (PCM8, Medical Systems Corporation, Digitimer, Welwyn Garden City, UK) and recorded on magnetic tape. Each record was replayed onto an eight-channel chart recorder (Graphtec WR3600) at 60 mm min^{-1} to allow inspection of the waveform patterns. Signals were passed also to a second AD converter into respiratory logging software (Cardas version 2.07, Oxcams, Oxford) sampling at 20 Hz. Each patient provided approximately 6 h of recorded data.

The waveforms were compared by taking successive 10-s blocks of data of the TTI and rib cage impedance signals. In each 10 s, samples of each signal were obtained at 5 Hz, giving 50 values. Each value was subtracted from the following one to give the relative changes of each signal which were then correlated by least squares linear regression (SPSS 4.0 for Unix V/386 Intel 80386). The strength of the correlation gave an index of the similarity of the two signal waveforms. These correlation estimates are presented as discrete values in the figures that have expanded time scales. For each patient, the correlation values of each 10-s block were plotted using a time scale of 40 cm h^{-1}. A typical short section of such a plot is shown in figure 1. The general pattern of these values was either a consistent excellent correlation with *r* values greater than 0.8, with occasional transient decreases in the *r* value; or periods of time when the *r* values were variable and consistently less than 0.8. If the *r* value was less than 0.8 for more than 30% in any 5 min this was termed "poor matching" and these periods measured for each patient. The chart records were inspected to determine the reason for the poor correlation, and classified into two categories: patient movement, recognized by a short (1–5 min) episode where all

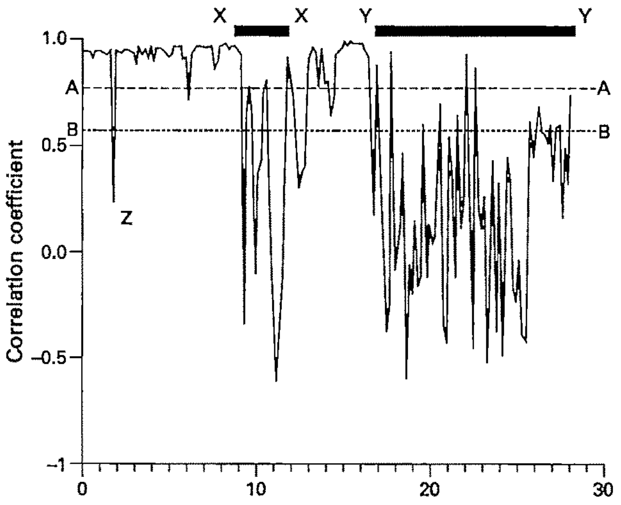

Figure 1 A sample of successive correlation plot illustrating the method of analysis. The horizontal bars (X–X, Y–Y) represent times when the correlation coefficient was less than 0.8 (line A–A) for more than 70% of the time. The first bar (X–X) indicates a period of 3 min caused by movement, and the second (Y–Y) a persistent period of poor matching. At the start of the plot, there was a transient episode of loss of correlation (Z) (r<0.6, line B–B).

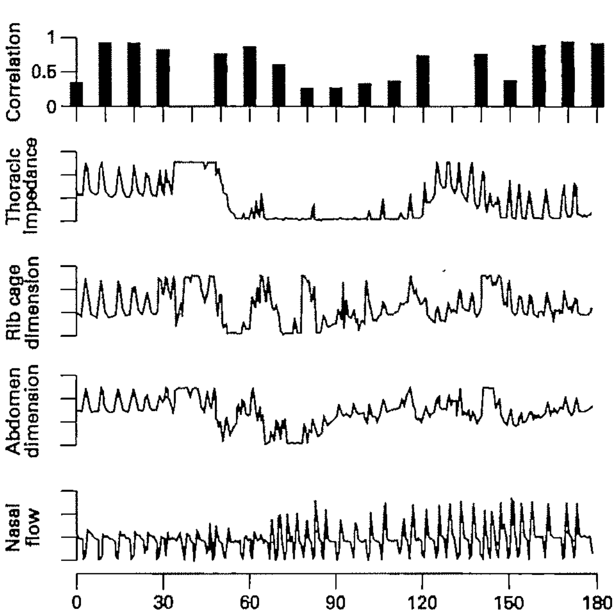

Figure 2 A plot of successive correlation values and the measured variables during a period of patient movement. Note also the poor nasal flow at the start of the trace, before arousal at about 30 s.

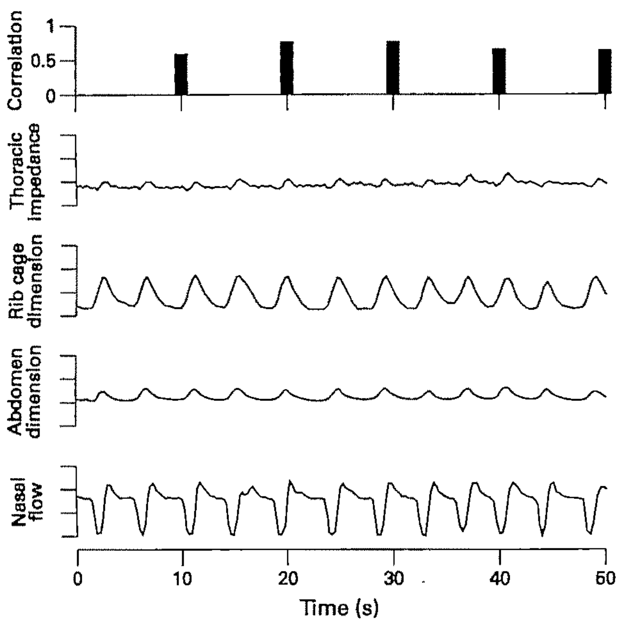

Figure 3 Poor correlation associated with a TTI signal which is biphasic and of low amplitude.

signals became markedly disturbed; or a poor relationship between the TTI and inductance band waveform shapes. In these latter periods, a signal with an unclear and complex waveform was classified as "abnormal" (usually a decrease in amplitude or a biphasic pattern). Results are presented for either one, or both, signals being of this type.

In the rest of the recording, when matching of the signals was generally good, episodes of transient decrease in the *r* value could occur when *r* became less than 0.6, usually for only one or two values. Each of these events was identified, related to the chart recording of the original signals and classified according to the apparent reason for the poor correlation. The respiratory pattern of the patient was inferred from the nasal flow signal leading up to the event, in relation to the rib cage and abdominal inductance signals, and classified as showing: apnoea, normal nasal flow pattern, mild or severe obstruction of nasal flow, or an abnormally large breath (usually after an episode of obstruction). Obstruction to flow was also recognized by a change in the waveform of the nasal flow signal. The TTI and inductance band signals were classified into one of the following categories: absent or low amplitude signal, stable waveform, change in baseline (successive cycles having different amplitude of turning points), large change in signal amplitude, change in waveform or signal waveform that was opposite in phase to the other signals (paradoxical waveform). The relationships between these states for the three signals were investigated by logical analysis using Minitab PC version 8.2 run using DOS 6.2.

Results

We studied 10 patients (five females), mean age 68 yr and weight 89% of expected (range 72–100%). The waveforms were poorly matched for a mean of 94 min (table 1). Motion artefact accounted for 11 min of poor matching. An episode of movement is shown in figure 2. Inadequate waveform matching accounted for the remainder of the time that the signals were poorly matched. The TTI waveform was poor on average for 58 min per patient. Both signals were poor for a mean of 16 min. An episode when the TTI signal was poor is shown in figure 3. TTI amplitude was small and the wave was biphasic in comparison with rib cage and abdomen inductance band signals. Four of 10 subjects were responsible for the majority of the poor TTI signals: 58, 129, 141 and 185 min, respectively.

There was no apparent relationship between the method of analgesia and the inadequate waveform. Periods of poor waveform generally started and

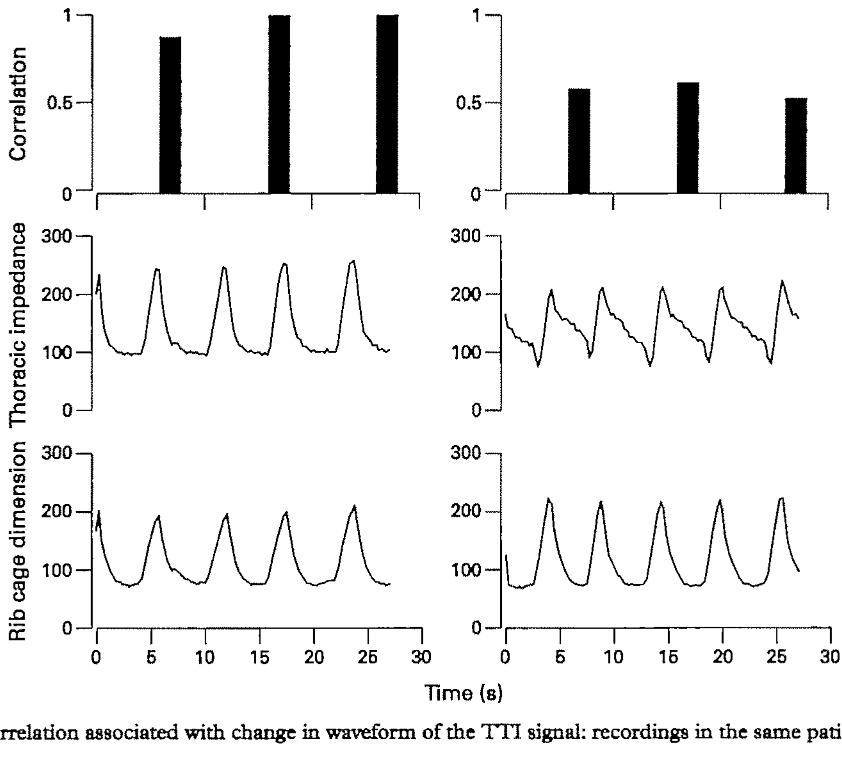

Figure 4 Change in correlation associated with change in waveform of the TTI signal: recordings in the same patient, the second 15 min after the first.

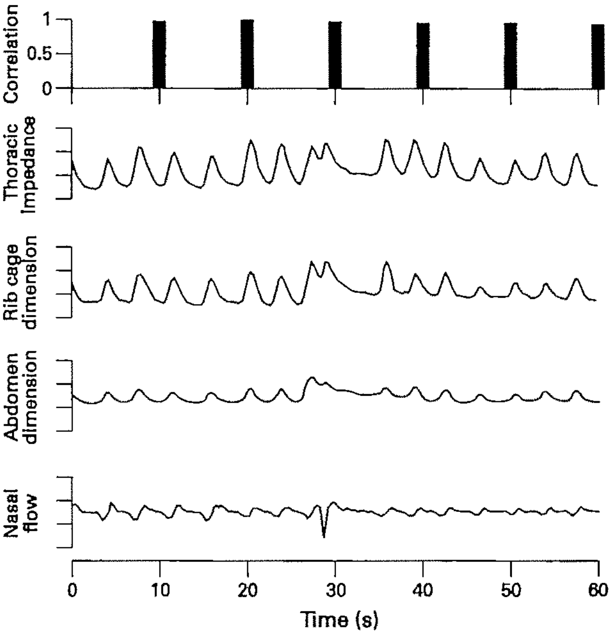

Figure 5 Persistently good correlation despite disturbances in waveform of both TTI and inductance signals.

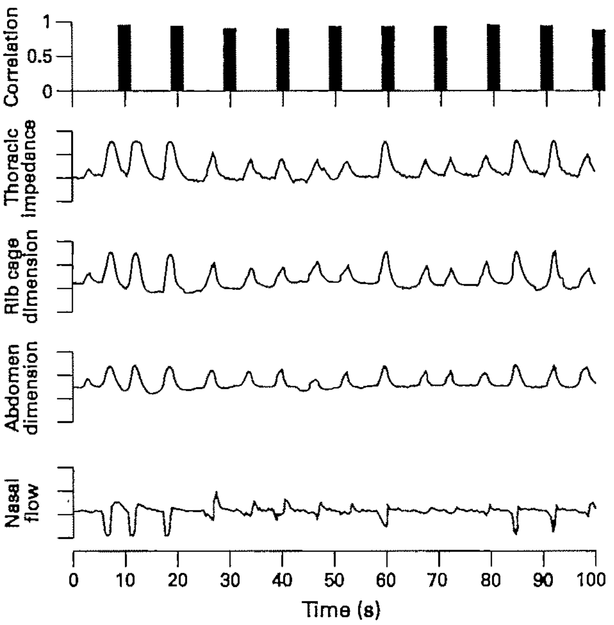

Figure 6 Persistently good correlation despite disturbances in breathing pattern and airway obstruction.

ceased with episodes of movement, probably indicating times when the patient moved into a different position. Figure 4 shows a change in correlation after a period of movement in a patient. The poor matching is associated with a change in the TTI waveform which shows a decrease in thoracic impedance at the onset of inspiratory flow.

If the correlation of waveforms was satisfactory (r >0.8 for >70% of the time), the correspondence between TTI and rib cage inductance band signals was very good, even when there were transient changes in the pattern of respiration (fig. 5) or episodes of airway obstruction (fig 6). Episodes of severe airway obstruction resulted in transient reduction in correlation, either because of changes in waveform (fig. 7) or changes in the signal baseline (fig. 8).

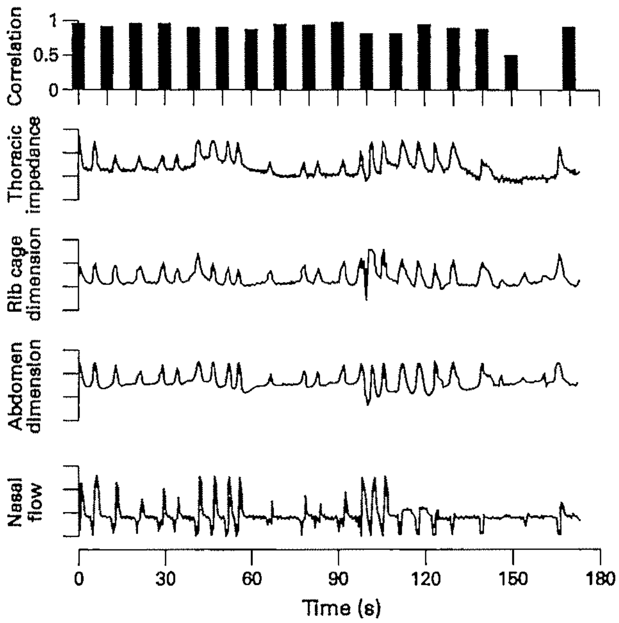

Figure 7 Repeated episodes of airway obstruction resulting in changes in waveform and baseline, and reduced correlation.

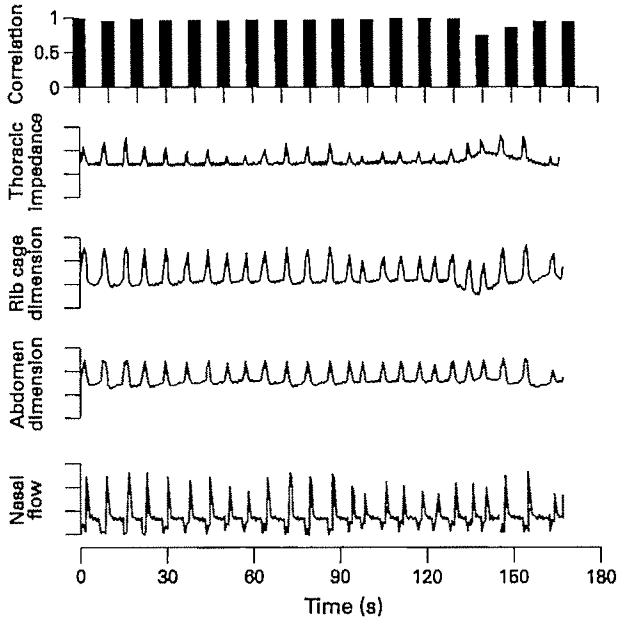

Figure 8 A minor episode of airway obstruction at 90–150 s with disturbances in TTI and inductance baseline and reduced correlation.

There were a total of 390 episodes of transient poor correlation in the 10 patients, with patients showing between 9 and 81 episodes of this type (table 2). More than 50% were associated with airway obstruction. Large breaths after an episode of obstruction accounted for 18% of events. In 17% of transient poor correlation events, there was no abnormality in the nasal flow signal. Baseline position change of the TTI signal most frequently reduced the correlation (45% of episodes), for example with airway obstruction (fig. 8). Changes in waveform of the TTI signal caused 25% of episodes, and in 19% there was no clear fault. Most commonly, the inductance band signal associated with a transient reduction in the correlation did not change (34% of episodes). The baseline changed in 25% of the episodes, the waveform altered in 15% and a small signal was present in 13%.

Absent airway flow and no signal from the TTI trace (which could indicate central apnoea) was noted only once. During inspection of the paper records it was evident that satisfactory correlation values could persist despite minor disturbances in the baselines of the signals, and in the signal waveform and amplitude, such as in figure 8. The traces were not examined systematically for this, as objective criteria for such events would have been difficult to establish.

Discussion

Chest wall impedance has been used to monitor respiration for many years[20]. The early development of the method has been reviewed by Pacela[21]. Realizing that independent movements of rib cage, abdomen and trunk contribute to lung volume changes[10] and that TTI is related to rib cage dimension[22] has tempered the hope that TTI could be related directly to lung volume, although alternative approaches using electrode arrays may provide more information on lung volume[23–25]. Comparisons of TTI with other methods have only been for short periods of time, often for only a few minutes[18]. We set out to use TTI to indicate chest wall movement and thus classify abnormalities of breathing. We have found from studies of oesophageal pressure in such patients that the most frequent respiratory abnormality is obstructive apnoea. In this case, the rib cage inductance band signal remains in phase with respiratory efforts, whereas abdominal movements may cease or become paradoxical[2]. Nasal flow often changed abruptly. In this study we are reasonably confident therefore that the decreases in flow represented obstruction rather than hypopnoea (when the flow waveform was attenuated but of similar shape) or change to mouth breathing (which we found to be almost always only expiratory).

For comparison, we used inductance bands. If the output signal is AC-coupled to remove baseline fluctuations, this method gives a long-term satisfactory qualitative index of movement, being disturbed only when the patient changes position. In this study, the inductance band system was judged to give a poor signal for a single prolonged episode (114 min) in only one subject and in 15% of the isolated events of poor correlation. However, inductance bands and TTI obviously detect different physical characteristics, and some of the discrepancies we found may be caused by other but nevertheless "real" changes, such as intrathoracic fluid shifts, which alter TTI measurements. Visual inspection and previous experience of the relationship between lung volume and chest wall dimension measurements led us to classify the simpler waveforms as "correct" although this is to some extent arbitrary.

Table 2 Incidence of abnormal waveforms associated with transient poor correlation. Values are percentage of total episodes of poor correlation

	TTI	Inductance
Abnormality		
Small wave	3	13
Normal	19	34
Baseline shift	45	25
Abnormal waveform	25	15
Other	8	13

The frequency of breathing was generally approximately 15 (range 7–30) bpm. Consequently, the sample rate of 5 Hz used gave 10–40 samples for each breath, usually 20. More rapid sampling would give small increments between successive values that could be affected by noise in the signals. With 10 s for each correlation, we compared the correspondence of the waveform over approximately two breaths which is probably what is done when comparisons are "by eye", and the number of samples was sufficiently great to ensure a good chance of detecting correlation. We detected three types of loss of correspondence between the signals. The first type, classified as movement artefact, disturbed both signals equally. The second type, poor waveform correspondence, was often judged to be the "fault" of the TTI signal: only on one occasion did the inductance method give a poor signal. Finally, there were frequent events when there was temporary loss of correlation between the signals. However, inspection of these events showed that on most occasions the TTI signal remained "interpretable". The most common reason for poor correlation was a baseline shift. The TTI apparatus we used was intended for measurement of the duration of inspiration and expiration of each breath and had an extended low frequency response for this purpose, and this reduced its capacity to recover from baseline changes. A reduction of the low frequency response of the TTI system would reduce the incidence of these episodes.

In 25% of cases, the baseline shift was associated with an episode of obstruction, and it may be that the shift was caused by changes in blood volume in the chest during obstruction. Another common reason for poor correlation was a change in waveform (99 of 390 events), and an uninterpretable signal was present on only four occasions. The method we used of testing for waveform comparability gives false positives: occasions when the TTI signal, alone, could be useful but the comparability of the waves was poor. The false negative rate, when the correspondence between the signals may have been poor but the correlation method did not indicate this, is probably small. We had no automated method or specific criteria for identifying false negative events, but carefully examined each chart, several times, without finding this possibility.

Studies of respiratory movement are generally for short measurement periods[26–30]. Overnight studies measuring respiratory movement or gas flow are uncommon, the study of Catley and colleagues being an exception[1]. They measured chest wall movements and interpreted paradoxical movements as airway obstruction, but gave no details of how much time satisfactory signals were absent. In another study using a simplified inductance band system, 14 of 63 records were excluded because of inadequate quality, and artefacts occurred at 0.2–0.7 per hour, which is a very low rate compared with this study. These were detected by inspection of the charts only, perhaps a less rigorous test of signal quality[3]. Similar studies by others, using inductance bands[31] or chest wall sensors[32], used computerized methods for analysis but provided no details of the means of validation of the data.

A more recent study[33] involved 20 patients, each studied both before operation and for 60–70 h after operation. An observer was present continuously to exclude artefact, but no details are provided of the proportion of record excluded.

We believe that our study is the first report of the quality of postoperative respiratory monitoring. The quality of these signals was affected by patient factors such as motion and also by technical factors such as electrode contact, position, and the position and stability of the inductance bands. Ideal signals would be obtained from a patient who slept in one position for the whole night: such a patient would certainly be over-sedated and likely to develop pressure sores, atelectasis and sputum retention (at least). Thus loss of signal is inevitable: breathing should not be a completely continuous process. Clinical investigations require differentiation of central and obstructive apnoea and this can be done with an index of the presence or absence of respiratory movements and a nasal flow signal. This study showed that TTI can provide this index, and as TTI measurements are simpler than inductance band methods, larger numbers of patients may be studied more easily.

Acknowledgements

This study was funded by a grant from the Scottish Hospital Endowments Research Trust, by W. J. Underwood's testamentary trust and a grant from the Association of Anaesthetists of Great Britain and Ireland. Professor J. A. W. Wildsmith was instrumental in obtaining the major funding for the study.

Preoxygenation in children using expired oxygraphy

P. J. Butler, H. M. Munro and M. B. Kenny

Summary

We performed preoxygenation on 25 patients, aged 1–12 yr. End-tidal oxygen sampling was used to find the duration of preoxygenation required to reach an end-tidal oxygen fraction of 0.9. All children reached this end-point within 80 s, which was markedly more rapid than that observed in adult subjects. The clinical applications of this form of monitoring in children are discussed. (*Br. J. Anaesth.* 1996;**77**:333–334)

Key words

Anaesthetic techniques, preoxygenation. Anaesthesia, paediatric. Children. Monitoring, oxygen.

Preoxygenation of the lungs is an important component of rapid sequence induction of anaesthesia and in many instances is part of routine anaesthetic practice. It reduces the risk of hypoxia during apnoea after induction of anaesthesia by providing a reservoir of oxygen in the patient's functional residual capacity (FRC). Although there have been many studies on the period required for preoxygenation, none has measured alveolar gas concentration in the paediatric population. Recent work has established respiratory oxygraphy as a reliable and non-invasive measure of end-tidal oxygen fraction ($F\text{E}'_{O_2}$)[1 2]. The purpose of this study was to determine the duration of preoxygenation required in paediatric patients to achieve an $F\text{E}'_{O_2}$ of 0.9.

Patients and methods

After obtaining Ethics Committee approval, informed parental consent and patient assent, where appropriate, we studied 25 patients, aged 1–12 yr, ASA I–III, before induction of general anaesthesia. Premedication comprised midazolam 0.2 mg kg^{-1} intranasally at the discretion of the anaesthetist. Exclusion criteria included intracardiac shunting, active respiratory disease (including upper respiratory tract infection within 2 weeks), acute abdominal disease, known difficult airway or craniofacial abnormality such that an anaesthetic mask could not be applied to the face. Mean age was 4.1 (range 1–12) yr and mean weight was 20.9 (SD 14.2) kg.

A circle absorber system was flushed with 100% oxygen and a flow rate of 6 litre min^{-1} was used for the study. A clear anaesthetic face mask (Vital Signs, Totowa, USA) of appropriate size was used. Subjects were laid supine and the mask was applied to produce a gas tight seal. If old enough to understand, subjects were instructed to breathe normally. Inspired and expired gases were sampled from immediately adjacent to the mask by a Rascal II monitor (Ohmeda, Salt Lake City, USA) calibrated according to the manufacturer's instructions. This device uses the Raman light scattering principle to measure anaesthetic and respiratory gases with a response time of less than 350 ms (10–90% rise time). $F\text{E}'_{O_2}$ was recorded every 10 s and preoxygenation proceeded until $F\text{E}'_{O_2}$ reached 0.9.

Results

Mean (95% confidence limits) $F\text{E}'_{O_2}$ values were calculated for each 10-s period from the start of preoxygenation and used to construct a graph of oxygen wash-in against time (fig. 1). It was found that 22 (88%) of the subjects reached an $F\text{E}'_{O_2}$ of 0.9 within 60 s and all reached this end-point within 80 s.

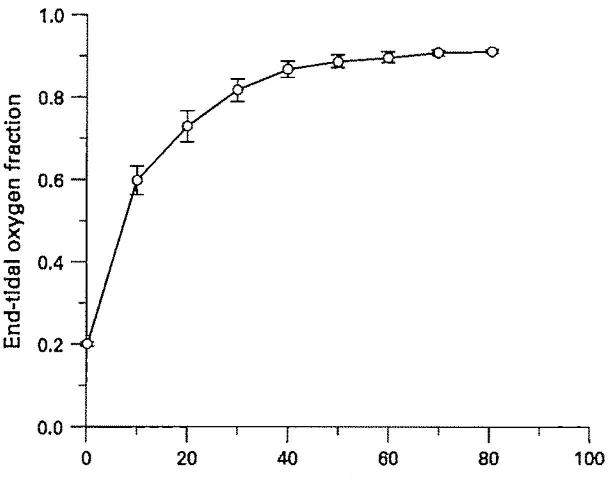

Figure 1 End-tidal oxygen fraction *vs* time for the 25 children during preoxygenation (mean, 95% confidence limits).

Discussion

There have been many studies of desaturation during induced apnoea after preoxygenation. Two studies of time for oxygen saturation to decrease to 90% in children showed that desaturation can occur rapidly, especially in small children, and that preoxygenation was useful in preventing this[3-4]. However, using time to desaturate is a poor method of defining the time required for adequate preoxygenation. Desaturation

Correspondence to P. J. B.

is affected not only by variations in oxygen wash-in to the lungs, but also by variables such as cardiac index and oxygen consumption[5]. It is also a delayed and retrospective measurement. Measurement of oxygen saturation during the preoxygenation process is of little value as saturation may be 99–100% while breathing room air.

End-tidal oxygraphy enables the anaesthetist to see on a breath-by-breath basis the success of the preoxygenation process. Studies in adults have shown that oxygen wash-in follows an exponential pattern and it has been proposed that the end-point for adequate preoxygenation should be an $F\mathrm{E}'_{\mathrm{O}_2}$ of 0.9[1 2]. The remaining 0.1 fraction consists mainly of carbon dioxide and nitrogen. Compared with pulse oximetry, an advantage of using respiratory oxygraphy lies in the fact that it is a real-time measurement and reveals variations in oxygen wash-in between patients. It is also a sensitive detector of poor mask fit in that air entrainment is recognized immediately and can be rectified[6].

We have shown that preoxygenation to an $F\mathrm{E}'_{\mathrm{O}_2}$ of 0.9 was possible within 80 s in all patients. This finding is in contrast with studies in 40 healthy adults[1] and 200 adult elective surgical patients[2] in whom 20% and 23%, respectively, of subjects had not reached an $F\mathrm{E}'_{\mathrm{O}_2}$ of 0.9 within 180 s. More rapid oxygen wash-in would be expected in children. Tidal volume, deadspace and FRC values in children are similar to those of adults when related to body size, but children have a higher ventilatory frequency[5]. Closing volumes are not reached during the course of normal expiration in children, unlike in the case of older adults.

Children may be less compliant than adults with a prolonged period of preoxygenation. Expired oxygraphy enables the anaesthetist to monitor alveolar gas concentrations precisely so that induction of anaesthesia can occur as soon as $F\mathrm{E}'_{\mathrm{O}_2}$ reaches the desired level. There is a theoretical benefit in continuing preoxygenation after an $F\mathrm{E}'_{\mathrm{O}_2}$ of 0.9 has been reached as poorly perfused organs may take longer to equilibrate with the alveolar oxygen fraction.

In summary, we have shown that all children attained an $F\mathrm{E}'_{\mathrm{O}_2}$ of 0.9 with 80 s of preoxygenation. We have also demonstrated the value of expired oxygraphy in the assessment of optimal preoxygenation on an individual patient basis. When suitable monitors are unavailable we suggest that a sensible duration of preoxygenation in healthy children should be not less than 60 s, paying attention to technique to produce a good mask seal and prevent air entrainment.

Intubating conditions and time course of rocuronium-induced neuromuscular block in children

T. FUCHS-BUDER AND E. TASSONYI

Summary

We have investigated the potential of rocuronium 0.6 mg kg^{-1} (2×ED$_{95}$) and 0.9 mg kg^{-1} (3×ED$_{95}$) for rapid sequence induction in 100 children, aged 3–7 yr. Intubating conditions with the two different doses of rocuronium were assessed in 70 children (n=35 in each group) undergoing elective surgery. Intubation was carried out by mimicking rapid sequence induction, and intubation conditions were evaluated according to a standard score. Intubating conditions were good to excellent in all 70 patients investigated (2×ED$_{95}$: excellent 29, good 6; 3×ED$_{95}$: excellent 33, good 2). In another 30 children (n=15 in each group), we examined the times of rocuronium-induced neuromuscular block using electromyography. Lag time and recovery index did not differ significantly between the two groups (lag time: 37 (SD 12) *vs* 33 (14) s; recovery index: 9 (3) *vs* 10 (4) min). Three times the ED$_{95}$ induced deeper neuromuscular block, 1 min after injection compared with 2×ED$_{95}$ (twitch height: 42 (24) *vs* 25 (19)%, respectively; P<0.05). The same was true for onset time (193 (47) *vs* 118 (23) s; P<0.01), clinical duration (21 (4) *vs* 34 (11) min; P<0.01) and duration to 75% recovery (30 (6) *vs* 44 (4) min; P<0.01). By mimicking rapid sequence induction, both doses of rocuronium offered clinically acceptable (good or excellent) intubating conditions. (*Br. J. Anaesth.* 1996;**77**:335–338)

Rocuronium bromide is a new steroidal nondepolarizing neuromuscular blocking drug, related structurally to vecuronium. This compound is characterized by a rapid onset and intermediate duration of neuromuscular block[1,2]. The rapid onset of action of rocuronium was the subject of several investigations determining if this compound allows rapid sequence induction. In adult patients, good to excellent intubating conditions were reported[3-5]. Crul and colleagues found that increasing the dose of rocuronium from 0.6 to 0.9 mg kg^{-1} improved conditions for rapid sequence induction[6]. Unfortunately they did not provide any information on whether or not this increase changed the time course of neuromuscular block, a well known phenomenon with other neuromuscular blockers[7]. In four of 40 patients undergoing elective Caesarean section, Abouleish and colleagues found clinically unacceptable intubating conditions after administration of rocuronium 0.6 mg kg^{-1}[8]. Thus, this suggests that 2×ED$_{95}$ of rocuronium is not sufficient for rapid sequence induction. The only published study using rocuronium for intubation in children was reported by Woelfel and co-workers[9]. However, the use of rocuronium in children for rapid sequence induction has not been evaluated to date. This question is of clinical interest because of the recent controversy on the use of suxamethonium in children[10,11].

The aim of this study was to investigate intubating conditions with two different doses of rocuronium (0.6 and 0.9 mg kg^{-1}) in children. Intubating conditions were investigated by mimicking rapid sequence induction. In addition, we assessed the time course of rocuronium-induced neuromuscular block.

Patients and methods

The study was approved by the institutional Ethics Committee and informed consent was obtained from the children's parents. We studied 100 children, ASA I or II, aged 3–7 yr, undergoing elective surgery. Patients were excluded if they were known to have neuromuscular disease or were receiving medications known to influence neuromuscular function. All patients were premedicated with midazolam 0.2 mg kg^{-1} orally, 1 h before induction of anaesthesia.

We first assessed the quality of rocuronium neuromuscular block in the context of rapid sequence induction. Seventy patients were allocated randomly to one of two groups of 35, to receive either rocuronium 0.6 mg kg^{-1} (2×ED$_{95}$) or 0.9 mg kg^{-1} (3×ED$_{95}$). Anaesthesia was induced with alfentanil 10 μg kg^{-1} and thiopentone 5 mg kg^{-1} followed by the dose of rocuronium according to patient group. Rocuronium was injected over 5 s. Sixty seconds after the end of injection, the trachea was intubated in all patients by the same experienced anaesthetist blinded to the treatment. He assessed intubating conditions using the following criteria[3]: excellent=jaw relaxed, vocal cords abducted and

T. FUCHS-BUDER, MD, E. TASSONYI, MD, Department of Anaesthesiology, Pharmacology, and Surgical Intensive Care, Division of Anaesthesiology, Geneva University Hospital, 24, rue Micheli-du-Crest, CH-1211 Geneva 14, Switzerland. Accepted for publication: April 24, 1996.

Correspondence to T. F.-B.

immobile, and no diaphragmatic movement; good=jaw relaxed, vocal cords abducted and immobile, and some diaphragmatic movement; poor=jaw relaxed, vocal cords moving, and coughing; and inadequate=jaw not relaxed and vocal cords closed. Cricoid pressure was applied during insertion of the tube. In addition, intubation time (time from start of intubation until definitive placement of the oral tube) was determined in both groups.

In the second part of the study we investigated the time course of rocuronium-induced neuromuscular block, comparing doses of 2xED$_{95}$ with 3xED$_{95}$. Thirty children were allocated randomly to one of two groups of 15. In both groups anaesthesia was induced with alfentanil 10 μg kg^{-1} and thiopentone 5 mg kg^{-1}, and maintained with isoflurane (1% end-tidal concentration) and 60% nitrous oxide in oxygen via a face mask. End-tidal carbon dioxide concentration was maintained at 4.5–5 vol% (Normocap, Datex Instrumentarium Corporation, Finland). Neuromuscular transmission was assessed by electromyography (Relaxograph, Datex Instrumentarium Corporation, Finland) at the right ulnar nerve–hypothenar muscle using transcutaneous electrodes. Measurements started when anaesthesia had been induced. The Relaxograph was set to deliver supramaximal stimuli (0.1 ms duration) of train-of-four (TOF) at 2 Hz every 20 s. The first of the four evoked responses was considered the twitch height. To minimize movement-induced changes in twitch response during electromyography, the patient's hand was fixed carefully. When the end-tidal isoflurane concentration had stabilized, the Relaxograph was re-calibrated and control twitch height measured. Patients then received either rocuronium 0.6 or 0.9 mg kg^{-1}. Administration of rocuronium was synchronized with the Relaxograph, with completion of injection concomitantly at the end of control TOF stimulation. The following times of neuromuscular block were measured: lag time=time between administration of rocuronium and the first measurable neuromuscular effect (twitch depression ≥5% of control value); twitch height at 1 min = twitch height 1 min after administration of rocuronium; onset time=time between administration of rocuronium and maximum twitch depression; clinical duration (CD)=time between administration of rocuronium and recovery to 25% twitch height; recovery index (RI)=time from 25% to 75% twitch height recovery; and duration 75 (D75)=time between administration of rocuronium and recovery to 75% twitch height.

End-tidal carbon dioxide concentration, temperature over the adductor pollicis muscle and isoflurane concentration were maintained stable during the whole study (4.5–5 vol%, ≥35 °C and 0.8–1%, respectively). Patients did not receive additional neuromuscular blockers until recovery to 95±5% twitch height. Patients in whom twitch height did not recover to control levels were excluded.

The Mann–Whitney *U* test was used for statistical comparison of the times of neuromuscular block induced by the two different doses of rocuronium. Intubating conditions were analysed using the chi-square test. All values, except intubation scores, are expressed as mean (SD). For statistical comparisons, differences were considered significant when $P<0.05$.

Table 1 Patient data (mean (SD or range))

	Intubating conditions		Time course	
Rocuronium	0.6 mg kg^{-1}	0.9 mg kg^{-1}	0.6 mg kg^{-1}	0.9 mg kg^{-1}
n	35	35	15	15
Age (yr)	5 (3–7)	5 (3–7)	5 (3–7)	5 (3–7)
Weight (kg)	20.7 (4.8)	20.9 (4.5)	20.7 (3.3)	19.7 (3.4)

Thiopentone (mg kg^{-1})	5.0 (0.18)	4.99 (0.17)
Alfentanil (μg kg^{-1})	9.78 (0.75)	9.94 (0.63)
Rocuronium (mg kg^{-1})	0.60 (0.02)	0.90 (0.02)

Results

The study groups did not differ in age or weight (table 1).

Intubating conditions obtained with both rocuronium 2xED$_{95}$ and 3xED$_{95}$ were clinically acceptable (e.g. excellent or good) (table 2). There were no differences in the frequency distribution of excellent or good intubation conditions between the two groups: after 2xED$_{95}$, intubating conditions were excellent in 29 patients and good in six; after 3xED$_{95}$, intubating conditions were excellent in 33 patients and good in two. Intubation was performed within 12.5 (3.4) s after 2xED$_{95}$ and within 11.6 (2.7) s after 3xED$_{95}$. The doses of drugs used for rapid sequence induction were comparable in both groups (table 3): thiopentone (5.0 (0.18) *vs* 4.99 (0.17) mg kg^{-1}) and alfentanil (9.78 (0.75) *vs* 9.94 (0.63) μg kg^{-1}; respectively).

After rocuronium, twitch height recovered to control levels in all 30 patients included in this part of the study. Lag time did not differ between the two doses (37 (12) *vs* 33 (14) s; respectively) but after 3 × ED$_{95}$ onset time was found to be faster (193 (47) *vs* 118 (23) s; $P<0.01$), clinical duration longer (21 (4) *vs* 34 (11) min; $P<0.01$), duration until 75% recovery of twitch height longer (30 (6) *vs* 44 (4) min; $P<0.01$) and neuromuscular block at 1 min greater (42 (24) *vs* 25 (19)% twitch height, $P<0.05$).

Table 4 Time course of neuromuscular block (mean(SD)). Lag time = Time between injection of the neuromuscular blocker and first measurable neuromuscular effect; Onset time = Time between injection of the neuromuscular blockers and maximal block; Twitch height at 1 min = Twitch height 1 min after the end of injection of the neuromuscular blocker; CD = Clinical duration; RI = Recovery index; D75 = Duration until 75% recovery of twitch height; $^{*}P < 0.05$; $^{**}P < 0.01$

	Rocuronium	
	0.6 mg kg^{-1} (n=35)	0.9 mg kg^{-1} (n=35)
Lag time (s)	37 (12)	33 (14)
Onset time (s)	193 (47)	118 (23)**
Twitch height at 1 min (%)	42 (24)	25 (19)*
CD (min)	21 (4)	34 (11)**
RI (min)	9 (3)	10 (4)
D75 (min)	30 (6)	44 (4)**

Recovery index was similar in both groups: 9 (3) min after 2xED_{95} and 10 (4) min after 3xED_{95} (table 4).

Discussion

We have investigated for the first time the potential of rocuronium for rapid sequence induction in children. The doses of rocuronium represented 2xED_{95} and 3xED_{95} for this age group[9]. The most important finding was that after both rocuronium 2xED_{95} (0.6 mg kg^{-1}) and 3xED_{95} (0.9 mg kg^{-1}), intubating conditions evaluated at 60 s after administration of the neuromuscular blocking agent were good to excellent (table 2).

There is some controversy on whether or not measurement of end-points such as onset time is meaningful in the context of defining optimal intubating conditions. Agoston stated that "onset time has become overestimated as a predictive parameter for the rate of development of adequate intubating conditions", and "is not a meaningful, quantifiable end-point defining optimal intubating conditions"[12]. Conversely, Magorian, Flannery and Miller "have chosen to monitor twitch tension as an end-point defining optimal intubating conditions, because this technique is quantifiable and reliable"[5]. Intubation score is the principal measure in the context of rapid sequence induction, as it indicates whether or not the patient's airway can be adequately secured reliably. Measurement of the time course of neuromuscular block is also important because information on onset characteristics (e.g. lag time, twitch height at 1 min and onset time) are complementary to information provided by the intubation score. However, both intubating conditions and time course of neuromuscular block are influenced by the depth of anaesthesia[8 13]. To overcome this problem in the context of measurement of the time course of neuromuscular block, re-calibration of the Relaxograph is needed when steady state concentration of the volatile anaesthetic is achieved. Any additional change in inspired concentration may directly influence the results[14] thus compromising the relevance of the data. With regard to intubating conditions, only those drugs needed for rapid sequence induction should be given, with no drug supplement before the tracheal tube is inserted and intubating conditions scored[15]. We evaluated both intubation score and times of rocuronium-induced neuromuscular block. In order to overcome the methodological problem described, we evaluated intubating conditions and neuromuscular pharmacodynamics in separate groups of patients.

Thus in the first part of the study we investigated the potential of rocuronium for rapid sequence induction, using it strictly according to the scenario for rapid sequence induction but in elective cases. Factors affecting intubation conditions, such as the dose of hypnotic[16] or opioid[17], were controlled in a very narrow range (table 3), and were comparable between both groups. No volatile anaesthetic or other drug supplement was given until after intubation. In all 70 patients, the trachea was intubated rapidly and without difficulty, and intubating conditions were clinically acceptable (table 2). In the group receiving 3xED_{95}, a trend towards a higher frequency of excellent intubating conditions was found. However, this difference was not statistically significant.

It would be of interest to compare intubating conditions after rocuronium with those after suxamethonium, the gold standard for rapid sequence induction. However, in view of the controversy on the use of this compound in elective paediatric anaesthesia[10 11], and clinical practice in our institution which limits suxamethonium to paediatric emergencies, we dismissed this possibility. In our opinion, these two drugs should be compared in children undergoing emergency intubation, where the use of suxamethonium is generally accepted.

To date, there are few data available on intubating conditions with rocuronium in paediatric patients. In a study of 12 children, intubating conditions 60 s after rocuronium were found to be excellent in nine and good in three patients[9]. Unfortunately the authors did not provide information on the potential of rocuronium for rapid sequence intubation, as intubating conditions were evaluated under steady state halothane anaesthesia. In adults, there is one published investigation on the potential of rocuronium for emergency intubation, using it strictly according to the scenario for rapid sequence induction but still in elective cases[6]. These authors found a higher frequency of excellent intubating conditions when the dose of rocuronium was increased from 0.6 to 0.9 mg kg^{-1}. They concluded that the higher dose of rocuronium should be used for "real" rapid sequence induction. This conclusion was supported indirectly by the results of Abouleish and colleagues who found in four of 40 patients undergoing Caesarean section poor or inadequate intubation conditions 60 s after rocuronium 0.6 mg kg^{-1}[8].

In the second part of this study, we measured the time course of neuromuscular block after rocuronium 0.6 and 0.9 mg kg^{-1} in children. Particular attention was given to assessing the onset characteristics of rocuronium. These were assessed measuring lag time, twitch height at 1 min and onset time. In a study in adult patients, Wierda and colleagues[18] found that the lag time of rocuronium was less than that of vecuronium; neuromuscular block was initiated in less than 40 s, which is important in situations where rapid control of the airway is required. However, in this study, an increase in the dose of rocuronium from 0.6 to 0.9 mg kg^{-1} did not lead to further acceleration of lag time. In addition, the initial progression of rocuronium-induced neuromuscular block was fast, leading to advanced motor block 1 min after injection of rocuronium, at the moment when rapid sequence intubation takes place. This phenomenon was more pronounced after the higher dose. In contrast with these findings, the onset time of rocuronium was not particularly fast in our patients. This confirms the findings of Wierda and colleagues who reported that rocuronium has an onset time comparable with that of vecuronium[18]. It is the rapid initial development of neuromuscular block which distinguishes rocuronium from other non-depolarizing neuromuscular blocking agents, and this may explain the favourable intubating conditions observed.

The duration of action of rocuronium was found to be intermediate after both 0.6 and 0.9 mg kg^{-1} (table 4). Increasing the dose of rocuronium also increased its duration of action. This increase was statistically significant, but should not be clinically relevant as the profile of the drug did not change. Moreover, the recovery index was not affected by the increase in dose. These results are in accordance with those reported in the same age group by Woelfel and colleagues[9].

We conclude that in children, rocuronium at both doses investigated offered good to excellent intubating conditions for rapid sequence induction in elective patients. Whether or not the intubating conditions of either rocuronium 0.6 or 0.9 mg kg^{-1} are comparable with those of suxamethonium should be investigated in real emergency situations.

Influence of induction technique on intubating conditions after rocuronium in adults: comparison with rapid-sequence induction using thiopentone and suxamethonium

H.J. SPARR, S. GIESINGER, H. ULMER, M. HOLLENSTEIN-ZACKE AND T.J. LUGER

Summary

We have assessed the effect of anaesthetic technique on intubating conditions after rocuronium 0.6 mg kg^{-1} in four groups (n=25 each) of unpremedicated patients in whom anaesthesia was induced with either thiopentone 5 mg kg^{-1} or propofol 2.5 mg kg^{-1} alone, or supplemented with alfentanil 20 μg kg^{-1}. Fifty control patients were anaesthetized with thiopentone followed by suxamethonium. Laryngoscopy was commenced at 45 s. Overall intubating conditions after rocuronium were similar to those after suxamethonium (good and excellent ≥96%) only when alfentanil was part of the induction regimen. However, intubation time was similar in all five groups and averaged 55 (SD 3.2) s, and the tube could be passed through open vocal cords within 70 s. After rocuronium the response of the diaphragm to intubation was more pronounced in the two groups of patients not receiving alfentanil (P<0.0001) and in patients anaesthetized using propofol with alfentanil (P<0.01) than in the control group. Opioids (in doses equivalent to alfentanil 20 μg kg^{-1}) constitute an integral part of an induction regimen containing rocuronium 0.6 mg kg^{-1}, regardless of whether or not thiopentone or propofol is used, in order to achieve overall intubating conditions similar to those after suxamethonium. (*Br. J. Anaesth.* 1996;**77**:339–342)

Key words

Anaesthetic techniques, induction. Intubation, tracheal. Neuromuscular block, rocuronium. Neuromuscular block, suxamethonium. Anaesthetics i.v., thiopentone. Analgesics opioid, alfentanil.

Rocuronium offers the fastest onset of action of all clinically available non-depolarizing neuromuscular blocking agents. Intubating conditions at 60 s after administration of rocuronium 0.6 mg kg^{-1} have been reported to be similar to those after suxamethonium[1–3]. This similarity in intubating conditions is surprising, because the onset of action of rocuronium at the laryngeal adductor muscles is slower than that after suxamethonium, and the degree of block at these muscles is less intense[4].

Anaesthetic techniques used in previous studies[1–3], in particular the use of opioids, may have improved intubating conditions after rocuronium. When increasing doses of opioids were added to propofol, intubating conditions were similar to those after suxamethonium, even in the absence of a neuromuscular blocking agent[5 6]. Propofol rather than thiopentone may further facilitate intubation, as propofol was shown to depress laryngeal reflexes to a greater extent than thiopentone in comparable doses[7]. When anaesthesia was induced with thiopentone alone in unpremedicated adult patients, intubating conditions produced by rocuronium were less favourable than those produced by suxamethonium[8].

Consequently, we hypothesized that opioids should be used with an induction regimen containing rocuronium in order to achieve tracheal intubation within 60 s. In addition, we were interested in whether or not intubating conditions after rocuronium are more favourable if anaesthesia is induced with thiopentone rather than with propofol. Therefore, in this study we administered rocuronium to four groups of unpremedicated patients in whom anaesthesia was induced in a rapid-sequence manner, either with thiopentone or propofol alone, or supplemented with the opioid alfentanil. Rapid-sequence induction with thiopentone and suxamethonium was used in a control group.

Patients and methods

The study was approved by the Ethics Committee of the Medical Faculty of the University of Innsbruck. After obtaining written, informed patient consent, we studied 150 subjects, ASA I–II, aged 18–65 yr, undergoing minor elective surgery (orthopaedic or gynaecological) under general anaesthesia. None of the patients had a history of malignant hyperthermia or were receiving any medications known to interact with neuromuscular blocking agents. Pregnant patients were excluded. A careful physical examination was performed to exclude patients with potential airway problems.

STUDY DESIGN

Patients were allocated randomly to one of five study groups. In the control group, 50 patients received

Correspondence to H. J. S.

thiopentone 5 mg kg^{-1} and suxamethonium 1 mg kg^{-1} in a rapid-sequence manner. Rocuronium 0.6 mg kg^{-1}, twice its ED95, was administered to four other groups of patients (25 patients in each group) in whom anaesthesia was induced with either thiopentone 5 mg kg^{-1} (group T-R) or propofol 2.5 mg kg^{-1} (group P-R) alone, or supplemented with alfentanil 20 μg kg^{-1} (groups AT-R and AP-R). The main variables assessed in these patients were intubation time and intubating conditions.

ANAESTHETIC TECHNIQUE

Patients did not receive premedication. After 3 min of preoxygenation, anaesthesia was induced in a rapid-sequence manner (not applying cricoid pressure) with thiopentone or propofol followed by suxamethonium or rocuronium. When alfentanil was part of the induction technique, it was administered immediately before the i.v. anaesthetic. All drugs were given into a rapidly running infusion of lactated Ringer's solution. Injection times were 10 s for alfentanil and thiopentone, 15 s for propofol, and less than 5 s for rocuronium and suxamethonium. Heart rate (determined by ECG), non-invasive arterial pressure, arterial oxygen saturation (Sp_{O_2}) and endtidal carbon dioxide concentration were monitored in all patients (Cardiocap, Datex, Finland).

TRACHEAL INTUBATION

A tracheal tube (Mallinckrodt Lo-Pro, Mallinckrodt Laboratories, UK) with an internal diameter of 8.5 cm in males and 7.5 cm in females was used. A flexible plastic mounted stylet was inserted into the tube. The same fully trained anaesthetist ("intubator"), who was blinded to the treatment each patient received, performed all intubations using a Macintosh size 4 blade. In order to prevent the intubator from noting suxamethonium-related muscle fasciculations, the intubator was called to enter the study room 40 s after administration of the blocker, and another 5 s later he was instructed to start intubation. The tube was intended to be placed in the trachea as soon as possible, but only when the vocal cords were open and immobile. Otherwise insertion of the tube was delayed until the vocal cords were open and immobile.

ASSESSMENT OF INTUBATION TIME AND INTUBATING CONDITIONS

Intubation time was recorded as the number of seconds from the end of administration of blocker to insertion of the tube in the trachea, as measured by a stop-watch. Intubating conditions were assessed using the criteria of Cooper and colleagues[9] (table 1). In addition, the occurrence of suxamethonium-related muscle fasciculations and movement of the limbs during and immediately after intubation were noted by both the attending anaesthetist and the intubator.

STATISTICAL ANALYSIS

Summary statistics (sample size, mean (SD)) were calculated for all quantitative variables of each group. We used one-way analysis of variance to compare age, weight and height between the five groups, and the chi-square test to compare distribution by sex. In order to evaluate differences between the control and each of the other groups, intubation time was analysed using the Mann–Whitney *U* test, and intubating conditions assessed using the chi-square or Fisher's exact test. Estimation of sample size was based on the results of a previous study[8] in which 60% of patients receiving rocuronium and 92% of patients receiving suxamethonium showed excellent intubating conditions after rapid-sequence induction with thiopentone. Using a two-group chi-square test (0.05 two-sided significance level with a correction factor for the four comparisons, 80% power) the minimum sample size thus determined was 45 patients for the control and 23 patients for each of the groups given rocuronium. Calculations were carried out using the software package SPSS (version 6.0 for Windows, SPSS Inc., Chicago, IL, USA).

Table 1 Scoring of intubating conditions[9]. A total score of 8–9 = excellent; 6–7 = good; 3–5 = fair; 0–2 = poor

Score	Jaw relaxation (ease of laryngoscopy)	Vocal cords	Response to intubation
0	Poor (impossible)	Closed	Severe coughing or bucking
1	Minimal (difficult)	Closing	Mild coughing
2	Moderate (fair)	Moving	Slight diaphragmatic movement
3	Good (easy)	Open	None

Results

Mean age, weight and height of the 150 patients were 34 (range 18–55) yr, 69 (SD 12.0) kg and 172 (8.7) cm.

Intubation time was similar in all groups with a mean value of 55.0 (3.4) s. In seven patients (two patients in the control group, three in group T-R, and one each in groups P-R and AT-R) the tube was positioned after 60 s because of problems with laryngoscopy or closed and mobile vocal cords. However, in all patients the tracheal tube was passed easily through open vocal cords within 70 s. Intubating conditions approximately 60 s after suxamethonium (control group) were rated as excellent in 88% and good in 12% of patients. Intubating conditions 60 s after rocuronium differed between the control and groups T-R and P-R, but were similar between the control and groups AT-R and AP-R, in which alfentanil was given during induction of anaesthesia. In groups T-R and P-R, intubating conditions were rated as excellent in only 40% and 32%, good in 40% and 60%, and fair in 20% and 8% of patients, respectively ($P<0.0001$ *vs* control) (fig. 1).

Among the three variables contributing to assessment of intubating conditions, ease of laryngoscopy was similar in all patients. On average, laryngoscopy was judged to be easy in 80% and fair in 20% of patients. However, the condition of the vocal cords differed between the control group and rocuronium-treated patients who did not receive alfentanil (fig. 2). In addition, in groups T-R and P-R and also in

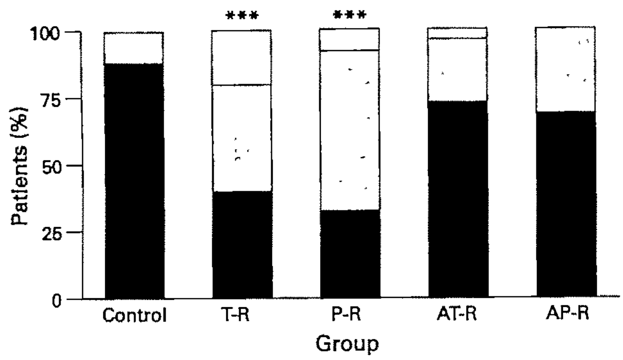

Figure 1 Intubating conditions after suxamethonium (control group; n=50) or rocuronium (groups T-R, P-R, AT-R and AP-R; n=25 each) after rapid-sequence induction using different anaesthetic techniques. Figure 2 Initial aspect of the vocal cords on laryngoscopy, ≥45 s after suxamethonium (control group; n=50) or rocuronium (groups T-R, P-R, AT-R and AP-R; n=25 each) after rapid sequence induction using different anaesthetic techniques. (Solid bars=open, lightly shaded bars=moving, open bars=closing, darkly shaded bars=closed.) ***P<0.001, group T-R compared with control; †P < 0.05, group P-R compared with control.

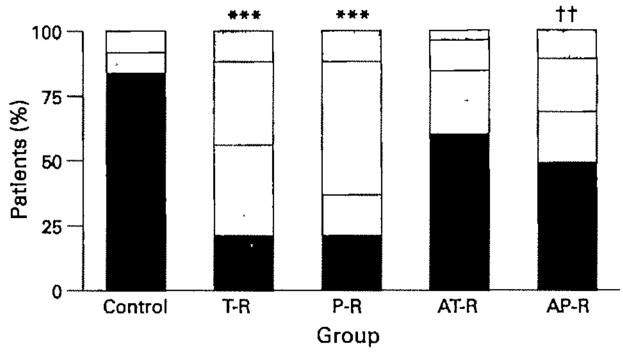

Figure 3 Response of the diaphragm to intubation after suxamethonium (control group; n=50) or rocuronium (groups T-R, P-R, AT-R and AP-R; n=25 each) after rapid-sequence induction with different anaesthetic techniques. (Solid bars=none, lightly shaded bars=diaphragmatic movement, open bars=mild coughing, darkly shaded bars=severe coughing.) ***P<0.0001, groups T-R and P-R compared with control; ††P<0.01, group AP-R compared with control.

group AP-R, the response of the diaphragm to intubation was more pronounced than in the control group (fig. 3).

Suxamethonium-related muscle fasciculations were not seen by the intubator, whereas the attending anaesthetist observed muscle fasciculations in 85% of patients given suxamethonium. During or immediately after intubation, or both, movement of the limbs (most frequently the hand, lower arm and foot) were observed in 8% of patients after suxamethonium, but in 40% of patients in group T-R (P<0.002 *vs* control), and 56% of patients in group P-R (P<0.001 *vs* control). In contrast, there was no difference in the incidence of movement of the limbs between the control and groups AT-R and AP-R, who were given alfentanil during induction.

Discussion

The results of this study indicated that in unpremedicated adult patients, intubating conditions after rocuronium were influenced by the induction technique. However, the anaesthetic technique used for induction of anaesthesia had no significant influence on intubation time after rocuronium 0.6 mg kg^{-1} compared with suxamethonium. Overall intubating conditions after rocuronium were similar to those after suxamethonium when alfentanil 20 μg kg^{-1} was part of the induction regimen. However, they differed from those after suxamethonium when anaesthesia was induced with either thiopentone or propofol alone in equipotent doses[10].

The findings of this study are supported by the results of previous studies in which intubating conditions after rocuronium were assessed. In one group of studies, where opioids were part of the induction regimen or used for premedication, intubating conditions at 60 s after rocuronium 0.6 mg kg^{-1} were similar to those after suxamethonium[1-3]. Although opioids and i.v. anaesthetics had no influence on the neuromuscular blocking effects of rocuronium[11], the use of opioids in these studies might have contributed to the favourable intubating conditions 60 s after rocuronium. After addition of increasing doses of alfentanil to propofol or thiopentone, both used as induction agents, intubating conditions became more favourable[6 12] and were even similar to those after suxamethonium[5 6]. However, when no neuromuscular blocking agent was administered, intubation failed in 50% of patients anaesthetized with propofol 1.5–2 mg kg^{-1} and alfentanil 1 mg^{1}.

In another set of two studies, intubating conditions were found to be less favourable after rocuronium than after suxamethonium[8 9]. In one of these studies, in unpremedicated adult patients, anaesthesia was induced in a rapid-sequence manner with thiopentone alone (6 mg kg^{1})[8]. In the other, patients were premedicated orally, and anaesthesia was induced with small doses of thiopentone and fentanyl and maintained with increments of these agents for approximately 10 min before rocuronium was administered[9].

Evidence suggesting that anaesthesia does have an impact on intubating conditions after rocuronium is supported by the findings of another study on rocuronium, in patients undergoing Caesarean section. The dose of thiopentone was increased from 4 to 6 mg kg^{-1}, and intubation was commenced at 80 s instead of 60 s in order to achieve good or excellent intubating conditions in 90% of patients[13].

In contrast with other investigators[1-3 9], we did not measure the time course of action of rocuronium, as the main purpose of this study was to challenge the efficacy of rocuronium in providing smooth intubating conditions within 60 s by using different techniques of induction of anaesthesia. In addition, until now no conclusive correlation between onset time at the adductor pollicis muscle and intubating conditions has been shown[14]. In our study, laryngoscopy revealed that the vocal cords were moving or closing in about 25% of rocuronium-treated patients who did not receive alfentanil during induction. The response of the diaphragm to intubation was more pronounced after rocuronium than after suxamethonium, but was attenuated by alfentanil (fig. 3).

These findings are supported by recent investigations[4 15 16]. The laryngeal adductor muscles and the diaphragm are more resistant to the effects of rocuronium than the adductor pollicis muscle[15 16]. However, the onset of action of small doses of rocuronium (0.4 and 0.5 mg kg^{-1}) at the laryngeal adductor muscles was shown to be faster than at the adductor pollicis muscle[4 16]. In contrast, the onset of rocuronium at the diaphragm was found to be slower than at the adductor pollicis muscle[15]. In addition, even after administration of higher doses of rocuronium (0.8 and 1.2 mg kg^{-1}), the onset of action at the laryngeal adductor muscles was slower than that after suxamethonium 1 mg kg^{-1} [4].

Hence, signs of incomplete neuromuscular block at the vocal cords, the diaphragm and other muscles may be observed more frequently after administration of rocuronium 0.6 mg kg^{-1} than after suxamethonium, if laryngoscopy with subsequent tracheal intubation is commenced at 45 s, in particular with a light plane of anaesthesia. In this study, movement of the limbs was noted only in exceptional cases after suxamethonium, and after rocuronium with alfentanil, but were observed frequently (≥40%) after rocuronium without alfentanil.

Spinal anaesthesia with 0.5% hyperbaric bupivacaine in elderly patients: effect of site of injection on spread of analgesia

B. Th. Veering, P. M. Ter Riet, A. G. L. Burm, R. Stienstra and J. W. van Kleef

Summary

In this randomized, observer-blind study, we have examined, in elderly patients, the effect of site of injection on analgesia levels after spinal injection of 0.5% hyperbaric bupivacaine solution. Thirty male patients, aged 68–87 yr, undergoing minor urological surgery during spinal anaesthesia received 3 ml of a 0.5% hyperbaric bupivacaine solution at either the L3–4 (n=15) or L4–5 (n=15) interspace. The solution was injected with the patient in the sitting position. The patient remained sitting for 2 min and was then placed in the supine horizontal position. Analgesia levels were assessed bilaterally using pinprick. The highest analgesia levels did not differ between groups (medians were approximately T7). There were no significant differences in the time to maximum cephalad spread of analgesia, maximum degree of motor block or haemodynamic changes. We conclude that injection at the L4–5 interspace has no advantage compared with injection at the L3–4 interspace. (*Br. J. Anaesth.* 1996;**77**:343–346)

Key words

Anaesthetic techniques, subarachnoid. Anaesthetics local, bupivacaine. Age factors.

Clinical studies have shown that the profile of spinal anaesthesia after subarachnoid administration of hyperbaric bupivacaine solutions changes with increasing age[1–3]. The highest level of analgesia extends approximately 3–4 segments higher in elderly compared with young adult patients. Age and higher levels of analgesia appear to be the main factors associated with the development of hypotension during spinal anaesthesia[4]. The degree of arterial hypotension after subarachnoid administration of local anaesthetics correlates with the level of sympathetic block, which is generally 2–4 spinal segments higher than the level of analgesia[5]. Therefore, it is important to limit the levels of analgesia and the associated levels of sympathetic block. This study was designed to determine and compare the levels of analgesia after injection of a hyperbaric bupivacaine solution at the L3–4 or L4–5 interspaces.

Patients and methods

We studied 30 male patients, ASA I–III, aged 68–87 yr, undergoing minor urological surgery under spinal anaesthesia. The study was approved by the Medical Ethics Committee of the University Hospital Leiden and verbal consent was obtained from all patients. Patients with diabetes, a history of neurological disease or coagulopathy were excluded. Patients were allocated randomly to receive 0.5% hyperbaric bupivacaine solution at either the L3–4 (group 1, n=15) or L4–5 (group 2, n=15) lumbar interspace. A randomization table was made before the start of the study and codes were stored in sealed envelopes, which were opened shortly before the extradural procedure.

Patients were premedicated with temazepam 10 mg orally and atropine 0.25 mg i.m., 45 min before induction of spinal anaesthesia. Before spinal injection, 500 ml of glucose in saline were administered by rapid i.v. infusion. The appropriate lumbar interspace was determined independently by two anaesthetists. The spines of the vertebrae were counted from both the cranial and caudal directions and the iliac crest was palpated to confirm the position of the fourth lumbar vertebra. Dural puncture was performed with the patient in the sitting position by a standard midline approach using a 25-gauge Quincke spinal needle via an 18-gauge introducer. When a free flow of clear cerebrospinal fluid was obtained and after aspiration of 0.2 ml of spinal fluid, 0.5% bupivacaine HCl 3 ml in 8% glucose (Marcaine heavy, Astra, Södertälje, specific gravity 1.026 at 20 °C) was injected at room temperature at a rate of 0.2 ml s^{-1}. Patients were kept sitting for 2 min after completion of the subarachnoid injection and were then placed in the supine horizontal position.

Analgesia was assessed bilaterally in the anterior axillary line by pinprick using a short bevelled 25-gauge needle. Assessments were made every 5 min during the first 30 min after injection and at 45 and 60 min thereafter. Analgesia was defined as inability to detect a sharp pinprick. When maximum cephalad spread of analgesia was produced, motor block of the lower limbs was assessed bilaterally using a modified Bromage classification by asking the patient to raise the extended leg, flex the knee and flex the ankle, and was rated per joint (0=no, 1=partial, 2=complete motor block). The results obtained on both extremities were added, giving a maximum score of 12 (complete motor block). The following

Bernadette Th. Veering, md, phd, Peter M. Ter Riet, md, Anton G. L. Burm, msc, phd, Rudolf Stienstra, md, phd, Jack W. van Kleef, md, phd, Department of Anaesthesiology, University Hospital Leiden, PO Box 9600, 2300 RC Leiden, The Netherlands. Accepted for publication: May 7, 1996.

variables were recorded: time to maximum cephalad spread of analgesia; highest level of analgesia; and degree of motor block. The study was observer-blind, that is the investigator assessing the level of analgesia and intensity of motor block was unaware of the site of injection.

Systemic arterial pressure, measured with an automatic cycling device (Accutor 1, Datascope, Helsinki, Finland) and heart rate (from the electrocardiogram) were monitored before injection, during induction, during surgery and in the recovery room at the following times: at 5-min intervals during the first 0.5 h and then at 15-min intervals until the patient was returned to the ward. If systolic arterial pressure decreased more than 30% below the preanaesthetic value or to less than 90 mm Hg, ephedrine 5 mg was given i.v. Bradycardia (heart rate <55 beat min^{-1}) was treated with atropine 0.25 mg i.v.

Group sizes were based on power analysis, which showed that with the variance in the highest level of analgesia observed in patients older than 65 yr in a previous study[2], 15 patients would be required per group to achieve an 80% probability of detecting a difference of two segments between the groups at the 0.05 level of significance. Data are presented as mean (SD), median (95% confidence intervals (CI)) or frequencies, as appropriate. Medians and confidence limits were corrected for the presence of tied observations[6]. Patient characteristics were analysed using the two-tailed, two-sample t test. Neural block characteristics were analysed with the two-tailed Mann–Whitney U test. Fisher's exact test was used for comparison of proportions. Haemodynamic data were examined using a repeated measurements analysis of variance design. Maximum changes in systolic arterial pressures (SAP) and heart rate (HR) were compared between groups using the two-tailed Mann–Whitney U test. $P<0.05$ was considered statistically significant.

Results

The groups were comparable in age, height and weight (table 1). Block characteristics are summarized in table 2 and were comparable between the groups. In all patients symmetrical analgesia levels were obtained. The median highest level of analgesia was T7.0 (CI T4.6–T9) in group 1 and T7.2 (T5.7–T8) in group 2 (fig. 1). Median times to reach the highest level of analgesia were 15.0 (CI 11.7–23.0) min and 16.4 (CI 10.0–19.3) min in groups 1 and 2, respectively. All patients in group 1 and 14 patients in group 2 achieved the maximum degree of motor block (score 12) before the start of surgery.

Analgesia was adequate for surgery in all patients. Changes in SAP and HR were similar in both groups (table 3). Two patients in group 1 and one patient in group 2 required ephedrine for treatment of hypotension. No patient developed post-spinal headache.

Discussion

Several studies have shown that analgesia levels obtained after subarachnoid injection of a hyperbaric local anaesthetic solution are approximately 3–4 spinal segments higher in elderly compared with young adults patients[1–3]. The same presumably holds for levels of sympathetic block that are associated with analgesia levels, but are generally 2–4 segments higher. Consequently, the highest levels of sympathetic block are often in the upper thoracic region in elderly patients, which may explain the higher

frequency of cardiovascular side effects in elderly compared with young adult patients[4,5]. Factors that contribute to the more extensive block in the elderly include gradual degeneration of the central and peripheral nervous system[7,8], changes in the anatomical configuration of the lumbar and thoracic spine[9], and possibly a reduction in the volume of the cerebrospinal fluid[10].

The main objective of this study was to determine if injection of a hyperbaric bupivacaine solution at a lower (L4–5) than usual (L3–4) lumbar interspace reduced cephalad spread of local anaesthetic solution and thereby limited the highest analgesia levels. The study was based on earlier observations which showed that a hyperbaric local anaesthetic solution produced bimodal spread when the patient was turned supine and remained on a horizontal plane after midlumbar (L3–4) subarachnoid injection. In this situation the solution is under the influence of gravity and migrates preferentially to the low levels of the subarachnoid space, that is below L3 in the lumbosacral concavity or above L3 in the thoracic concavity[11]. If, however, the epicentre of the injection lies at L4–5 in the declining portion of the lumbar lordosis, a greater portion of the solution may spread in a caudad direction. The study was encouraged by recent observations of Hirabayashi and colleagues[12] who examined the anatomical configuration of the spinal column in supine volunteers using magnetic resonance imaging (MRI). They demonstrated that the median highest point was not located at L3, as is commonly believed, but at L4 (range L3–4 to L4), explaining partly why a uniform dose of hyperbaric anaesthetic solution shows variable levels of analgesia when injected via either the L3–4 or L4–5 interspace. It should be emphasized, however, that Hirabayashi and colleagues studied younger patients (aged 16–63 yr). In elderly patients, such as in this study, the highest point may have migrated because of degenerative processes.

As it is well known that lumbar interspaces may be easily misidentified[13], identification in this study was made independently by two anaesthetists who counted the spines of the vertebrae from both the cranial and caudad directions and palpated the iliac crest to confirm the position of the fourth lumbar vertebra. Despite these precautions it is possible that misidentification occurred in some patients. More definite identification of the correct interspaces would have required x-ray marking. However, we abstained from such procedures for ethical reasons. Moreover, such identification techniques may invalidate the results for prospective use in routine clinical practice, where these techniques are not used.

The results of this study confirm that there is considerable spread in the highest levels of analgesia when a hyperbaric solution is administered to elderly patients. Furthermore, the results are in keeping with those of two earlier studies from our institute on the influence of age on the quality of neural block after subarachnoid administration of hyperbaric bupivacaine at the L3–4 interspace[2,3]. Median highest levels of analgesia in elderly patients (>65 yr) in those studies were approximately T9 and T7, respectively. The results of this study were, however, disappointing in that injection at the L4–5 interspace did not result in lower analgesia levels compared with injection at the L3–4 interspace, and haemodynamic changes did not differ between groups. The lack of effect of the site of injection on analgesia levels is consistent with the findings of Sundnes and colleagues[14], the only investigators who have reported on the effect of site of injection on analgesia levels attained with hyperbaric bupivacaine, and they observed no correlation between the site of injection (L2–3 or L3–4) and the highest level of analgesia. However, their study was designed primarily to study the effects of volume of injected solution and patients were not allocated randomly to the puncture site.

The effects of varying sites of injection have not been studied as extensively with hyperbaric as with plain bupivacaine solutions. However, with plain solutions there are discrepancies between studies that have examined the influence of different injection sites on analgesic spread[15-18]. There was no significant difference in maximal level of sensory block when plain bupivacaine solutions were injected in elderly patients at different levels, with patients in the sitting position during injection and until 2 min thereafter, when patients were turned supine[15,16]. In contrast, when solutions were injected with the patient in the lateral horizontal position and then turned immediately supine after injection, highest analgesia levels were 4 segments higher when the injection was at the L2–3 interspace compared with the L3–4 or L4–5 interspace[17,18]. Although comparisons between studies may be confounded by differences in the temperature of the injected solutions (room temperature *vs* body temperature), which affects baricity (at room temperature 0.5% plain bupivacaine is usually slightly hyperbaric, at body temperature usually slightly hypobaric, depending on the density of the CSF, which may vary between patients), these observations suggest that the effect of the site of injection is dependent on the positioning of the patient, at least with plain bupivacaine solutions.

Inflammatory changes after extradural anaesthesia may affect the spread of local anaesthetic within the extradural space

T. IGARASHI, Y. HIRABAYASHI, R. SHIMIZU, H. MITSUHATA, K. SAITOH, H. FUKUDA, A. KONISHI AND H. ASAHARA

Summary

We have assessed cephalad spread of analgesia in 491 patients undergoing extradural anaesthesia at the L2–3 or L3–4 interspace. Patients were classified into one of three groups based on the number of previous lumbar extradural anaesthesia procedures: none (group I, *n*=339), one (group II, *n*=82), and two or more (group III, *n*=70). Cephalad spread of analgesia was greater in group I than in groups II and III, regardless of the puncture site. In addition, we examined the extradural space using a flexible extraduroscope in 32 patients who were excluded from the analysis of spread. Extraduroscopy showed the extradural space to be patent in patients with no history of prior lumbar extradural anaesthesia, but it was not clearly identified in patients who had received extradural anaesthesia one or more times because of aseptic inflammatory changes, including proliferation of connective tissue, adhesions between the dura mater and the ligamentum flavum, granulation and changes in the ligamentum flavum. Extradural anaesthesia may cause aseptic inflammatory changes in the extradural space which may reduce the spread of analgesia. (*Br. J. Anaesth.* 1996;**77**:347–351)

Key words

Anaesthetic techniques, extradural. Equipment, extradural space indicators.

Repeat extradural anaesthesia has been reported to be unreliable compared with initial extradural anaesthesia, resulting occasionally in unilateral or failed block [1 2]. However, the reasons for the unreliability of repeat extradural anaesthesia have not been investigated thoroughly. Extraduroscopy provides a clear view of the lumbar extradural space [3 4]. Therefore, we have studied the effects of repeat extradural anaesthesia on the spread of analgesia and on extraduroscopic findings.

Patients and methods

The study was approved by the local Ethics Committee and informed consent was obtained from all patients. Data were obtained from 523 patients who received extradural anaesthesia for a variety of therapeutic or surgical procedures, including extracorporeal shock-wave lithotripsy, transurethral resection of the prostate and transurethral resection of bladder tumours.

In order to estimate the effects of repeated extradural anaesthesia on the spread of analgesia, we assessed cephalad spread of analgesia in 491 patients undergoing lumbar extradural anaesthesia performed at the L2–3 or L3–4 interspace. Patients were classified into one of three groups based on the number of previous lumbar extradural anaesthesia procedures: none (group I, *n*=161 (L2–3), *n*=198 (L3–4)), one (group II, *n*=33 (L2–3), *n*=56 (L3–4)) and two or more (group III, *n*=26 (L2–3), *n*=49 (L3–4)). Patients with a history of prior extradural anaesthesia of the cervical, thoracic or sacral region were excluded. Each patient was premedicated with hydroxyzine 25–50 mg. Patients were then placed in the right lateral decubitus position on a horizontal operating table. A 17-gauge Tuohy needle was introduced at either the L2–3 or L3–4 interspace using the paramedian technique. The extradural space was identified using loss of resistance with a small amount of air. When no cerebrospinal fluid or blood flowed from the needle, 2% mepivacaine 20 ml were injected into the extradural space via the needle over a period of 20 s. An extradural catheter (outside diameter 1 mm; Hakko, Tokyo, Japan) was inserted 5 cm in a cephalad direction into the extradural space, and the patient was placed in the supine position. Fifteen minutes after injection, the cephalad level of analgesia was determined using the pinprick test and referring to a dermatome chart[5] by pre-selecting the dependent side to record. Additional local anaesthetic was administered via the catheter 15 min after the initial injection if the level of analgesia was inadequate for the planned therapeutic or surgical procedure.

In order to evaluate the effects of repeated extradural anaesthesia on the extraduroscopic findings, we examined the lumbar extradural space in the other 32 patients. These patients underwent the

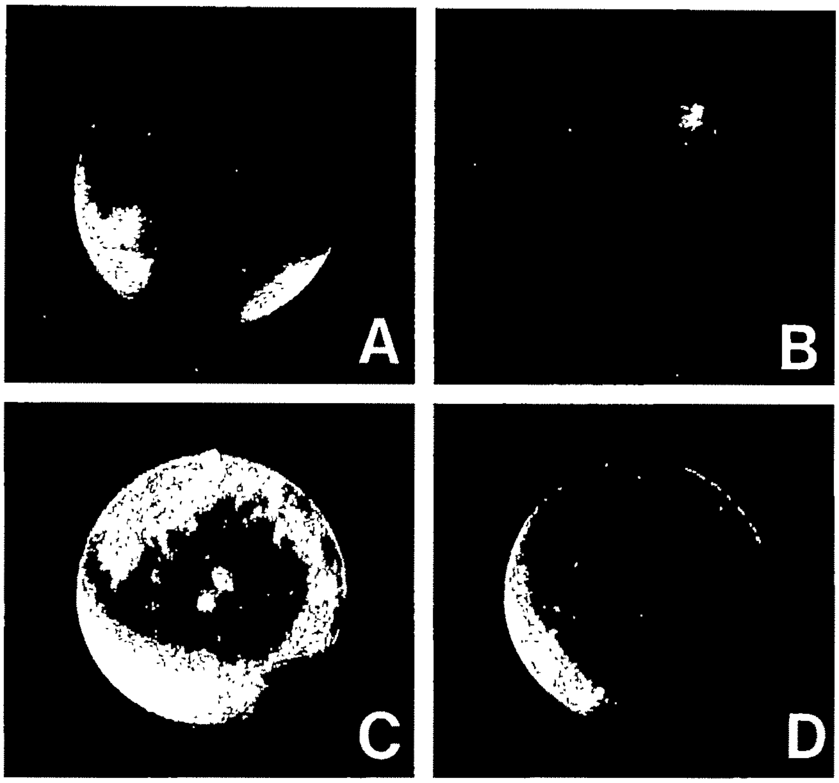

Figure 1 Photographs of the lumbar extradural space obtained by extraduroscopy in patients with no history of prior extradural anaesthesia. The views are cephalad. The extradural space in a 53-yr-old woman is observed as a patent canal (A). The upper part of the canal appears yellow and was identified as the ligamentum flavum. The lower part appears as a white membrane with associated blood vessels and was identified as the dura mater. Bleeding was induced by the introduction of the Tuohy needle in a 51-yr-old man (B). The connective tissue in a 55-yr-old woman was so fragile (C) that the extraduroscope was able to break it easily (D).

same technique of extradural puncture and additional examination of the lumbar extradural space with a flexible fibrescope, either 0.5 or 0.8 mm in diameter (Olympus AF type 5 or type 8, Tokyo, Japan) immediately after identifying the extradural space. The fibrescope was connected to a television monitor system (Olympus OTV-A and CLV-A, Tokyo, Japan) and introduced into the extradural space easily through the Tuohy needle. Patients who underwent extraduroscopy were excluded from analysis of spread.

Statistical analyses were performed with the StatView package version 4.02 (Abacus Concepts, CA, USA) on a Macintosh Quadra 650 (Apple Computer Inc., CA, USA). Age, weight and height are expressed as mean (SD or range), and values were compared using repeated measures analysis of variance after Dunn's procedure. The level of analgesia is expressed as median (range), and values were compared using the Kruskal–Wallis test after Mann–Whitney's *U* test. $P<0.05$ was considered statistically significant.

Results

Age, weight and height did not differ between the three groups of patients undergoing extradural anaesthesia at the L2–3 or L3–4 interspace (tables 1, 2). Cephalad spread of analgesia was greater in group I than in both groups II and III, regardless of the puncture site (tables 1, 2). There were no differences in cephalad spread of analgesia between groups II and III, regardless of the puncture site. Unilateral block was not observed in any of the patients examined.

Figure 1 shows typical photographs obtained via the extraduroscope in patients with no history of prior extradural anaesthesia. The extradural space in a 53-yr-old woman was observed as a patent canal (fig. 1A). The upper part of the canal appeared yellow and was identified as the ligamentum flavum. The lower part appeared as a white membrane with associated blood vessels and was identified as the dura mater. The introduction of the Tuohy needle induced bleeding in a 51-yr-old man (fig. 1B). The connective tissue in a 55-yr-old woman (fig. 1C) was

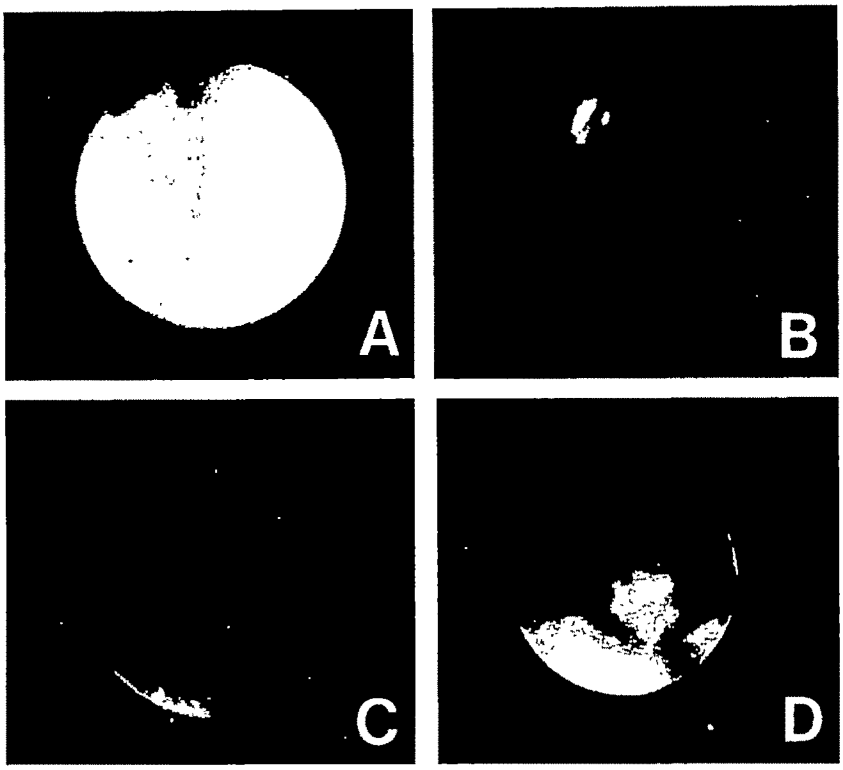

Figure 2 Photographs of patients with a history of previous extradural anaesthesia. Connective tissue has proliferated and the extradural space cannot be identified as a patent canal in a 67-yr-old woman with a history of three prior extradural anaesthesia procedures (A). When the endoscope was withdrawn, a channel was observed (B). Adhesions are seen between the dura mater and the ligamentum flavum in a 72-yr-old man who had undergone extradural anaesthesia 1 month previously (C). Granulation is seen in a 61-yr-old man who underwent extradural anaesthesia 3 months previously (D).

so fragile that the extraduroscope was able to break it easily (fig. 1D).

Figures 2 and 3 show typical photographs in patients with a history of previous extradural anaesthesia. The connective tissue had proliferated and the extradural canal could not be identified clearly in a 67-yr-old woman with a history of three prior extradural anaesthesia procedures (fig. 2A). The contents were a homogeneous fat pad without fibrous septation. It was possible to advance the extraduroscope through this connective tissue without resistance. When the extraduroscope was withdrawn, a channel produced by the scope was observed in the connective tissue (fig. 2B). Other extraduroscopic findings were as follows: adhesion between the dura mater and the ligamentum flavum in a 72-yr-old man who had undergone extradural anaesthesia 1 month previously (fig. 2C), granulation in a 61-yr-old man who had undergone extradural anaesthesia 3 months previously (fig. 2D), irregularities in the ligamentum flavum in a 68-yr-old man who had undergone extradural anaesthesia 1 month previously (fig. 3A) and irregular proliferation of connective tissue and blood vessels in a 64-yr-old man who had undergone extradural anaesthesia six times within a 3-yr period, the most recent 3 months previously (fig. 3B). This proliferation of connective tissue was seen to occlude the extradural space.

We encountered no accidental dural punctures and observed no signs of neurological injury in any of our patients.

Discussion

We have found that cephalad spread of analgesia was reduced in patients with a history of prior lumbar extradural anaesthesia, and extraduroscopic examination revealed significant inflammatory changes occluding the extradural space in these patients. These inflammatory changes may have affected the spread of local anaesthetic within the extradural space. Similar findings were observed in patients who had undergone only one prior extradural anaesthetic procedure, and the spread of analgesia in patients who had received extradural anaesthesia only once was similar to that in patients who had received extradural anaesthesia two or more times.

Repeated extradural anaesthesia has been reported to be unreliable in patients undergoing extracorporeal shock-wave lithotripsy[2]. In our study, we confirmed the reduction in cephalad spread of analgesia in patients undergoing repeated extradural anaesthesia. Why does repeat extradural anaesthesia become unreliable? We suggest that inflammatory changes in the extradural space, resulting from prior extradural anaesthesia, may play an important role in limiting cephalad spread of analgesia. In this study, the inflammatory changes observed included proliferation of connective tissue, adhesions between the dura mater and the ligamentum flavum, and granulation and irregularities in the extradural space. Proliferation of connective tissue, whether homogeneous or irregular, occluding the extradural space may hinder cephalad spread of anaesthetic. Adhesions between the dura mater and the ligamentum flavum may also interfere with spread. Granulation and irregularities in the extradural space may interfere with penetration of anaesthetic into the spinal nerve roots because the anaesthetic is absorbed through the connective tissue.

It should be noted, however, that this reduction in cephalad spread of analgesia was not observed in all patients undergoing repeat extradural anaesthesia.

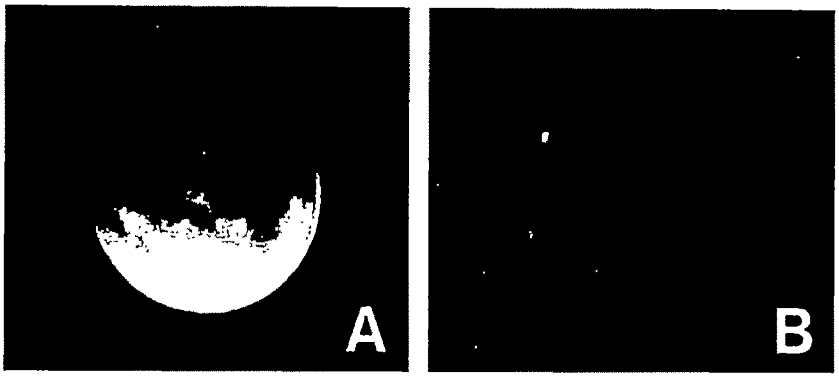

Figure 3 Photographs of patients with a history of prior extradural anaesthesia. Irregularities are seen in the ligamentum flavum in a 68-yr-old man who had undergone extradural anaesthesia 1 month previously (A). Irregular proliferation of connective tissue and blood vessels is observed in a 64-yr-old man who underwent extradural anaesthesia six times in a 3-yr period, the most recent 3 months previously (B).

Wide variations in the level of analgesia were seen in patients who underwent repeat extradural anaesthesia, and these variations were similar to those encountered in initial extradural anaesthesia. Inflammatory changes, including proliferation of connective tissue and adhesions between the dura mater and the ligamentum flavum, may play a role in limiting cephalad spread of anaesthetic. On the other hand, narrowing of the extradural space resulting from these inflammatory changes might be expected to increase cephalad spread of anaesthetic in repeat anaesthesia, as when the same volume of solution is injected into a narrower space, it might spread over a wider area. This may explain the observation that some patients with a history of prior extradural anaesthesia were found to have significant cephalad spread of analgesia. Therefore, the inflammatory changes in the extradural space alone cannot explain the variations in spread observed in patients undergoing repeat extradural anaesthesia. The specific findings observed by extraduroscopy may play an important role in determining the spread of local anaesthetics in extradural anaesthesia.

The absence of any differences in the spread of analgesia between groups II and III is extremely interesting, and suggests that inflammatory changes can be induced by a single extradural anaesthesia procedure. However, the connective tissue after initial extradural anaesthesia differed from that seen after repeat anaesthesia. In the former, the connective tissue was found to be fragile and elastic, whereas in the latter case, it was dense and hard. When the extraduroscope was withdrawn, these differences were immediately obvious. The connective tissue was more easily broken in the former than in the latter. In our patients, prior extradural anaesthesia always involved introduction of a Tuohy needle and a catheter, followed by administration of local anaesthetic. Inflammatory changes induced by the introduction of an extradural catheter have been demonstrated in both animals[6 7] and humans[8 9]. Administration of local anaesthetic alone may also cause inflammation[6-10]. In addition, bleeding induced by the introduction of the Tuohy needle was observed frequently in extraduroscopic examinations. The factors responsible for the inflammatory changes in the extradural space are unclear.

In assessing the results of this study, we should also consider the fact that the extradural space was observed after introducing a small amount of air. The extradural space is sometimes described as a potential space, rather than a true cavity[11 12]. The introduction of air may therefore have affected our extraduroscopic findings, expanding the extradural space and stretching the connective tissues. However, in our study, all patients received identical extradural punctures, and the effects of the air introduced into the extradural space should have been similar in all cases. Therefore, we believe that this factor had no influence on our comparative findings. In addition, patients who underwent extraduroscopy were excluded from the analysis of spread, because extraduroscopy made channels in the extradural space and broke down the adhesions, thereby altering the spread of drug in the extradural space.

The incidence of unilateral block after administration of local anaesthetic via a catheter has been reported to be higher in repeat block than in initial block[1]. In this study, we observed no unilateral block after administration of local anaesthetic via the needle. The laterality of the block may occur after administration of local anaesthetic via a catheter, presumably because of the misplaced catheter into the lateral side in the extradural space by aseptic inflammatory changes. Further observations are required.

In summary, extradural anaesthesia caused inflammatory changes characterized by proliferation of connective tissue, adhesions and granulation, and irregularities in the extradural space. These inflammatory changes may affect the distribution of local anaesthetic within the extradural space.

Acid–base state of cerebrospinal fluid during pregnancy and its effect on spread of spinal anaesthesia

Y. Hirabayashi, R. Shimizu, K. Saitoh, H. Fukuda and T. Igarashi

Summary

To assess the possible relationship between changes in acid–base state of cerebrospinal fluid (CSF) and enhanced spread of spinal anaesthesia during pregnancy, we have measured CSF pH, carbon dioxide tension ($P\text{co}_2$) and HCO_3^- values in 73 women undergoing spinal anaesthesia with hyperbaric amethocaine 8 mg. Patients were allocated to one of four groups according to gestational period: non-pregnant group (n=13), first trimester group (8–13 weeks, n=19), second trimester group (14–26 weeks, n=11) and third trimester group (27–39 weeks, n=30). The pH of the CSF was greater in the second and third trimester groups than in the non-pregnant group. CSF $P\text{co}_2$ decreased by 0.53–0.8 kPa throughout pregnancy. CSF HCO_3^- was decreased throughout pregnancy. Overall, no clinically significant correlation was found between maximum cephalad spread of analgesia and CSF pH, $P\text{co}_2$ or HCO_3^-. We conclude that pregnancy-induced changes in acid–base state of CSF have little effect on the spread of spinal anaesthesia, although there is a clinically different spread of spinal anaesthesia between non-pregnant and pregnant states. (*Br. J. Anaesth.* 1996;**77**:352–355)

The spread of regional anaesthesia is reported to be enhanced in pregnant compared with non-pregnant women[1–5]. Mechanical[6–8] and hormonal[9–11] changes have been implicated as possible factors for pregnancy-induced enhancement of regional anaesthesia. In addition, acid–base changes during pregnancy have been suggested to affect spread of extradural anaesthesia[5].

Cerebrospinal fluid (CSF) is in contact with the spinal cord and spinal nerve roots, and changes in acid–base state of CSF during pregnancy may therefore affect spread of spinal anaesthesia. Although many investigators reported acid–base state of arterial blood during pregnancy[12–16], there are few studies which have dealt with acid–base state of CSF in pregnant women. The purpose of this study was to see if changes in acid–base state of CSF correlated with enhanced spread of spinal anaesthesia during pregnancy.

Patients and methods

The study was approved by the Hospital Ethics Committee and informed consent was obtained from all patients. We studied 13 non-pregnant and 60 pregnant women. All patients, ASA I–II, had no major health problems and no contraindications to spinal anaesthesia. Patients were allocated to one of four groups according to gestational period: non-pregnant group (n=13), first trimester group (8–13 weeks, n=19), second trimester group (14–26 weeks, n=11) and third trimester group (27–39 weeks, n=30). Operative procedures included arthroscopic operation on the knee (n=13) in the non-pregnant group; procedures for cervical incompetency in the first (n=19) and second (n=11) trimester groups; and procedures for cervical incompetency (n=6) and Caesarean section (n=24) in the third trimester group.

None of the patients was premedicated. Patients were placed in the lateral position on a horizontal operating table. Under aseptic conditions, lumbar puncture was performed at the L3–4 interspace with a 25-gauge Quincke needle using a median approach. The needle was inserted with its bevel orientated parallel to the dural fibres and then rotated 90° to direct the bevel cephalad. To determine acid–base state of CSF, 1 ml of CSF was withdrawn just before administration of the drug. CSF pH, carbon dioxide tension ($P\text{co}_2$) and HCO_3^- were measured using a blood-gas analyser (178 pH/blood gas analyser, Ciba Corning Diagnostics, Boston, MA, USA) within 5 min. Amethocaine 8 mg in 2 ml of 10% glucose was given over 40 s. Lumbar puncture and sampling were performed by one anaesthetist who was unaware of the patient's group assignment, although he knew the type of surgery and abdominal girth. Immediately after spinal injection, patients were turned gently to the supine horizontal position. No attempt was made to influence the level of sensory block by manipulating the operating table. Patients undergoing procedures for cervical incompetency were placed gently in the horizontal lithotomy position, 30 min after spinal injection. Left uterine displacement was applied

Correspondence to Y. H.

to parturients undergoing Caesarean section until the beginning of the operation. A second anaesthetist who was blinded to the CSF data assessed the spread of analgesia bilaterally using pinprick at 5, 10, 15, 20, 30 and 60 min after spinal injection according to a dermatomal chart. If the analgesic level differed on each side, the average value was used for analysis. In 22 of the 73 patients, an aliquot of the CSF sample was provided for progesterone analysis, which has been reported previously[11].

Comparisons between the four groups were made by analysis of variance (ANOVA) followed by Fisher's protected least significant difference test for parametric data, and Kruskal–Wallis followed by Mann–Whitney *U* test for non-parametric data. Correlation between indices of acid–base state and maximum cephalad spread of analgesia was analysed using Spearman's rank correlation coefficient (ρ). $P<0.05$ was considered significant.

Results

There were no differences in age and height between the four groups (table 1). Median gestational age indicated that patient characteristics in the first trimester group clustered at the end of the range, second trimester group at the beginning of the range and third trimester group at the end of the range. The characteristics of the third trimester patients were similar gestationally to term parturients. Maximum cephalad spread of analgesia was higher in the second and third trimester groups than in the non-pregnant group. Times to maximum cephalad spread did not differ between the four groups (table 2).

CSF pH was greater in the second and third trimester groups than in the non-pregnant group (table 3). CSF pH did not correlate with maximum cephalad spread of analgesia (fig. 1A). CSF $P\mathrm{co}_2$ was decreased by 0.53–0.8 kPa below non-pregnant levels even during the early stages of pregnancy and was maintained at this decreased level for the remainder of the pregnancy (table 3). CSF $P\mathrm{co}_2$ correlated inversely with maximum cephalad spread of analgesia (fig. 1B). CSF $\mathrm{HCO_3}^-$ was decreased throughout pregnancy (table 3). CSF $\mathrm{HCO_3}^-$ correlated inversely with maximum cephalad spread of analgesia (fig.1C). Overall, although there were significant differences in the changes in CSF pH, $P\mathrm{co}_2$ and $\mathrm{HCO_3}^-$, changes in median values and ranges were such that these were unlikely to be clinically significant.

Discussion

We have shown that CSF $P\mathrm{co}_2$ began to decrease even in the early stages of pregnancy, and that CSF pH was unchanged during the early stages of pregnancy and then increased for the remainder of the pregnancy. These observations, however, are not surprising. Pregnancy induces an increase in minute ventilation to approximately 50% above non-pregnant levels[6]. This increase in minute ventilation, beginning early in the first trimester, decreases maternal Pa_{CO_2} from 5.33 kPa to approximately 4.0 kPa[12–14 16]. Arterial pH, however, remains near normal because of increased renal excretion of $\mathrm{HCO_3}^-$ [12–14]. The decrease in CSF $P\mathrm{co}_2$ and $\mathrm{HCO_3}^-$ may be a direct result of changing Pa_{CO_2} and lower $\mathrm{HCO_3}^-$ levels in arterial blood. Unlike arterial blood, increased CSF pH during the middle and later stages of pregnancy, observed in this study, suggests a partially compensated acid–base change from non-pregnant controls.

Local anaesthetic solution applied to a nerve membrane exits in two forms: the non-ionized base and the ionized cation[17]. The Henderson–Hasselbalch equation for the equilibrium determines the levels of ionized and non-ionized forms. An increase in pH increases the amount of local anaesthetic in the non-ionized base form, which should enhance the rate of diffusion across the nerve sheath and nerve membrane, resulting in a more rapid onset time of nerve block. In this study, CSF

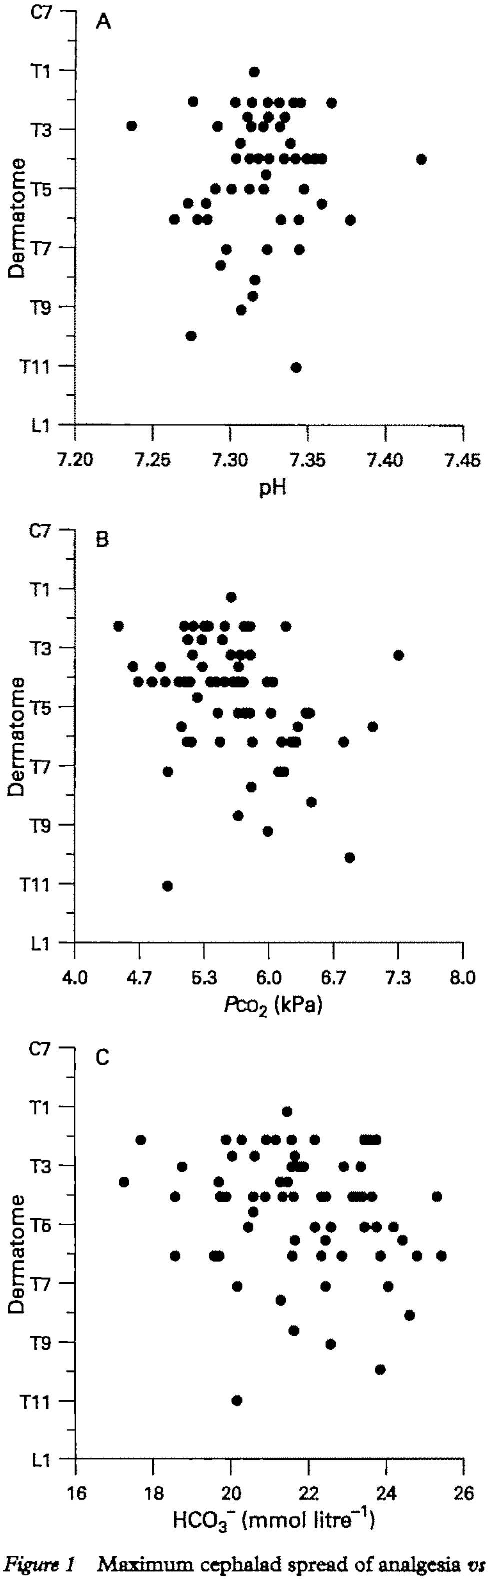

Figure 1 Maximum cephalad spread of analgesia *vs* CSF pH (A), Pco$_2$ (B) and HCO$_3^-$ (C). CSF pH did not correlate with maximum cephalad spread of analgesia (ρ=0.19, P=0.1). CSF Pco$_2$ correlated inversely with maximum cephalad spread of analgesia (ρ=−0.32, P<0.01). CSF HCO$_3^-$ correlated inversely with maximum cephalad spread of analgesia (ρ=−0.24, P<0.05).

pH was greater in the second and third trimester groups than in the non-pregnant group; maximum cephalad spread of analgesia was higher in the former than in the latter group. The increase in CSF pH may, in part, contribute to the observed enhancement of analgesia in the middle and late stages of pregnancy. However, the spinal cord and spinal nerve roots within the dural sac are not covered with sheaths, and thus diffusional delays may have little significance on local anaesthetic action when given directly into the CSF. In this study, CSF pH did not correlate with maximum cephalad spread of analgesia, and times to maximum cephalad spread did not differ between groups. To what degree the change in CSF pH contributed to the observed enhancement of analgesia in the middle and late stages of pregnancy could not be determined.

The presence of carbon dioxide has been reported to enhance both rate and potency of local anaesthetic action[17–21]. This effect is consistent with the ionized cationic form of local anaesthetics being the more active form. After penetration of the nerve sheath and nerve membrane, the non-ionized drug dissociates into the non-ionized base and the ionized cation. The quantity of each varies with the pH of the axoplasm. Carbon dioxide diffuses rapidly across the membrane and causes lowering of intracellular pH. A lowered pH increases the amount of local anaesthetic in the ionized cationic form, which should act as a potent blocker of sodium channels. The results of this study, however, demonstrated that CSF Pco$_2$ correlated inversely with maximum cephalad spread of analgesia. The reason for this inverse correlation is unclear. We speculate that enhancement caused by factors other than carbon dioxide may overshadow the effects of carbon dioxide[6–11].

A decreased buffering capacity during pregnancy has been suggested to explain enhanced extradural anaesthesia during the first trimester of pregnancy[5]. The decreased buffering capacity may allow the local anaesthetic to remain in a salt form for longer and, therefore, stay longer in the area of injection (extradural space). In this study, CSF HCO$_3^-$ was found to decrease during pregnancy. The degree of the decrease, however, was small, and hence local anaesthetics injected directly into the CSF might not be affected significantly. In addition, in accordance with the results of a previous study[4], we failed to demonstrate enhancement of spinal anaesthesia during the first trimester. Unlike extradural anaesthesia[5], spinal anaesthesia during the first trimester may not be affected by pregnancy-induced decreases in buffering capacity.

In contrast with spinal anaesthesia, alkalinization of local anaesthetics has been investigated in extradural anaesthesia. The investigators disagree about the efficacy of this preparation. Some authors reported faster onset and better quality of sensory and motor blocks[22–24]. Others have failed to show any clinical advantages of alkalinization over a plain solution[25–29]. Additional studies are needed to draw definitive conclusions on the onset of extradural anaesthesia with pH-adjusted local anaesthetics.

We showed higher levels of analgesia in pregnant women during the second and third trimesters compared with non-pregnant controls, but did not assess the onset of the block. Therefore, we could not draw any conclusions on the onset of block during pregnancy. However, it is believed that, as a rule, onset of spinal anaesthesia is more rapid during pregnancy. Pregnancy-induced changes, including curvature of the spinal column[7], soft-tissue anatomy within the spinal canal[6 8] and higher progesterone concentrations[11 30], have been implicated as possible factors for the enhancement.

A limitation of this study was the position of the patients examined. This study was performed in clinical patients undergoing various types of operation, but not in volunteers who can be kept in a uniform position throughout the observation. Patients undergoing procedures for cervical incompetency were placed in the horizontal lithotomy position, which is thought to decrease the height of spinal block[31]. However, the horizontal lithotomy position has been reported to have little effect on the height of the block[32 33]. In addition, left uterine displacement was performed in patients undergoing Caesarean section. It could be argued that this manoeuvre might alter the spread of the block but the counter argument would be that in the interest of neonatal well being, the manoeuvre was the best compromise.

Nausea and vomiting after cardiac surgery

C.R. GREBENIK AND C. ALLMAN

Summary

We have undertaken a prospective, randomized study to determine the incidence of postoperative nausea and vomiting during intensive care stay after cardiac surgery, and to study the effect of addition of droperidol to an infusion of morphine used for postoperative analgesia. Data from 398 patients were examined. The use of droperidol reduced complaints of nausea from 92 of 198 (46.5%) to 46 of 200 (23%) and episodes of retching or vomiting from 73 of 198 (36.9%) to 44 of 200 (22%). The number of patients requiring rescue antiemetic medication was also reduced significantly from 100 of 198 (50.5%) of those who did not receive droperidol to 44 of 200 (22%) of those given droperidol. Mean duration of intubation was 4.9 h and was unaffected by the use of droperidol. Droperidol had no effect on mean length of stay in the recovery unit. (*Br. J. Anaesth.* 1996;**77**:356–359)

Key words

Vomiting, nausea. Vomiting, nausea, surgical factors. Vomiting, incidence. Surgery, cardiovascular.

Nausea and vomiting are common and distressing symptoms during recovery from anaesthesia and surgery. Studies of postoperative nausea and vomiting (PONV) have concentrated frequently on women undergoing gynaecological procedures and there is little information on the incidence or management of nausea and vomiting after cardiac surgery.

The aim of this study was to assess the incidence of nausea and vomiting in the first 24 h after cardiac surgery, in a unit in which early tracheal extubation is usual[1]. In addition, we wished to ascertain if the addition of droperidol to a continuous infusion of morphine would reduce nausea and vomiting without causing excessive sedation and thereby increase the duration of tracheal intubation and postoperative mechanical ventilation.

Patients and methods

After obtaining approval from the hospital Ethics Committee, we collected data on 442 patients undergoing elective or urgent open heart surgery. Premedication with papaveretum or morphine (10–20 mg) together with hyoscine 0.2–0.4 mg was given i.m. approximately 1 h before surgery. All patients received supplementary oxygen from the time of premedication. After insertion of i.v. and arterial cannulae, anaesthesia was induced with fentanyl 10–15 $\mu g\ kg^{-1}$ and etomidate 5–10 mg. Neuromuscular block was produced with pancuronium and, after tracheal intubation, anaesthesia was maintained with halothane in oxygen and air until the start of cardiopulmonary bypass. Ventilation was adjusted to produce normocapnia. Anaesthesia during bypass was provided by continuous infusion of propofol 6 $mg\ kg^{-1}\ h^{-1}$ and after bypass by halothane in oxygen and air. At the end of surgery, neuromuscular block was antagonized with neostigmine and glycopyrronium and the patient transferred to the cardiac recovery unit (CRU).

After age and sex stratification, patients were allocated randomly to one of two groups: group A received an infusion of morphine 60 mg in saline 58 ml to which was added droperidol 10 mg; group B received a similar infusion of morphine to which 2 ml of normal saline were added. Both patients and nurses caring for them were unaware of the nature of the additive.

After reconnection of monitoring cannulae and initial stabilization in the CRU, the infusion of morphine was commenced. Patients with a body weight greater than 60 kg received an initial bolus dose of morphine 4 mg followed by an initial infusion of 2 $mg\ h^{-1}$, with boluses of 2 mg as indicated. Patients weighing less than 60 kg received an initial dose of 2 mg with an infusion of 1 $mg\ h^{-1}$ and a bolus of 1 mg. The infusion rate was adjusted at the discretion of the attending nurse. If analgesia was inadequate diclofenac 50–100 mg, by suppository, was given, provided there were no contraindications to its use. Patients' lungs were ventilated mechanically until the following criteria for a trial of spontaneous respiration and extubation were met:

1. stable cardiovascular system with an adequate cardiac output. The need for cardiovascular support with inotropic drugs or intra-aortic balloon pump was not a contraindication to extubation provided that haemodynamic state was stable or improving;
2. core temperature > 36 °C;
3. adequate gas exchange with Pa_{O_2} >10 kPa with FI_{O_2} of 50% or less; and
4. no excessive mediastinal bleeding.

The trachea was extubated if the patient was rousable and breathing was clinically adequate, with a ventilatory frequency <30 bpm and oxygen saturation >90% with FI_{O_2}<0.6. Mild hypercapnia ($P\text{CO}_2$

C.R. GREBENIK, FFARCS, C. ALLMAN, RN, Oxford Heart Centre, John Radcliffe Hospital, Oxford OX3 9DU.
Accepted for publication: April 24, 1996.

up to 7.5 kPa) was not a contraindication to extubation. After tracheal extubation patients were seated upright and allowed to breathe oxygen-enriched air.

If the patient did not meet the criteria for tracheal extubation and required sedation to tolerate intubation and ventilation, an infusion of propofol 1–4 mg kg^{-1} h^{-1} was commenced until another trial of spontaneous breathing was performed at the discretion of the nursing staff.

Data collected included patient age, sex, height, weight and operation. When patients were awake, the presence of nausea was ascertained by hourly questioning. Retching or vomiting and need for other antiemetics were noted. As retching is similar to vomiting in all aspects except the production of vomitus, we elected to examine both retching and vomiting together. A "vomiter" was thus any patient who had at least one episode of retching or vomiting. Rescue medication of metoclopramide 10 mg, by slow i.v. injection, was prescribed for all patients and given as required by the nurse caring for the patient. Observations were continued until patients were discharged to the ward on the following day. Duration of intubation, total cumulative dose of morphine administered in the recovery unit, and duration of stay within the recovery area were also noted.

Data were analysed using an unpaired *t* test for patient data and chi-square analysis for comparison of events between groups. $P<0.05$ was considered significant.

Results

Complete data were collected for 398 patients. Data were discarded from 21 patients who had a second anaesthetic for repeat sternotomy or died in the recovery unit, or whose trachea remained intubated for the whole of the first 24 h, and from 20 patients for whom data were incomplete. Data from three other patients who were receiving dialysis for chronic renal failure were also discarded. Age, body weight and sex distribution are shown in table 1. There were no significant differences between the two groups. Operative details are shown in table 2 and were similar for the two groups.

Mean stay in the CRU and therefore number of hours recorded was 21.9 h and was not significantly different between the two groups. Mean morphine consumption during this time was 29 (SD 11.3) mg, with maximum consumption of 60 mg and minimum consumption of 6 mg. There was no correlation between body mass index (weight (kg)/height $(m)^2$) and morphine consumption, or between age and morphine consumption. Mean duration of intubation was 4.9 (4.3) h and was not significantly different between the two groups (table 3).

Table 1 Patient characteristics (mean (range) or number)

	Group A (morphine + droperidol) (*n*= 200)	Group B (morphine + saline) (*n*= 198)
Age (yr)	62.2 (41–85)	62.3 (30–87)
Age of males (yr)	61.7	62.3
Age of females (yr)	63.7	62.4
Sex (M:F)	151:49	139:59
Body weight (kg)	76.9	75.3

No. affected by nausea	84 (29%)	54 (50%)
No. affected by retching or vomiting	66 (23%)	44 (41%)

Table 5 Effect of age on the incidence of postoperative nausea and vomiting

	Age (yr)					
	30-40 (*n*=3)	41-50 (*n*=34)	51-60 (*n*=114)	61-70 (*n*=150)	71-80 (*n*=91)	81-90 (*n*=6)
No. of patients with nausea (%)	3 (100)	14 (41)	38 (33)	50 (33)	32 (35)	1 (17)
No. of patients with retching or vomiting (%)	2 (67)	12 (35)	29 (25)	41 (27)	26 (29)	0 (0)

There were highly significant differences in the incidence of PONV between the two groups. Addition of droperidol to infusion of morphine was associated with a reduction in complaints of nausea from 92 of 198 (46.5%) to 46 of 200 (23%) and in episodes of retching or vomiting from 73 of 198 (36.9%) to 44 of 200 (22%). The number of patients requiring rescue medication was also significantly reduced from 100 of 198 (50.5%) of those not receiving droperidol to 44 of 200 (22%) of those given droperidol (table 3). There was no correlation between body mass index and propensity for nausea or vomiting.

When data were examined to investigate the influence of sex on nausea and vomiting, it became apparent that women were significantly more likely than men to suffer nausea, retching and vomiting (table 4). Although droperidol was effective in significantly decreasing retching and vomiting in women, it did not significantly reduce the incidence of nausea. This last observation may be related to the relatively small number of women in the sample, reducing the power of the measurement.

Data were also examined to assess the effect of age on PONV (table 5). There was a statistically significant reduction in the incidence of PONV in patients more than 80 yr of age.

Discussion

It is important to minimize vomiting and retching after surgery to avoid potential cardiovascular complications and to improve patient comfort and assist in rapid recovery. The latter is of particular importance with increasing financial pressure and the drive to reduce inpatient stay[2]. While there was no significant difference in the length of stay in the CRU between vomiters and non-vomiters, this is not surprising as PONV is unlikely to be a problem requiring an increase in the length of high dependency nursing.

Until about 6 yr ago it was our standard practice to sedate patients after cardiac surgery and to ventilate the lungs for a period of 12–16 h after operation. Nausea and vomiting were not perceived as particular problems with this regimen, and it is possible that a lengthy period of sedation and artificial ventilation reduced the incidence of postoperative emesis. More recently, we have tended to extubate the trachea much earlier after surgery[3] and have become increasingly aware of the problem of PONV. Our study has shown that using a moderate dose of fentanyl, and extubating the trachea within the first 6–8 h after cardiac surgery, the incidence of nausea was approximately 37% and that of postoperative retching or vomiting approximately 47%, despite the use of hyoscine as premedication. The overall incidence of nausea and vomiting was therefore of a similar order to that after other types of major surgery[4].

In common with Myles and colleagues[5], we have found that many of our patients are unable to use patient-controlled analgesia effectively in the first 24 h after cardiac surgery, and we therefore rely on a nurse-controlled regimen for the early postoperative period. Addition of droperidol to infusion of morphine reduced significantly the incidence of nausea and approximately halved the incidence of retching and vomiting. While it has been argued that prophylactic administration of antiemetics is unjustified[6], in view of the high incidence of PONV and its potential deleterious effects after cardiac surgery, the prophylactic use of droperidol has now become part of our standard practice.

Droperidol is a neuroleptic agent with potent dopamine receptor antagonist properties and is an effective antiemetic in a variety of doses. Bolus doses are contraindicated after cardiac surgery as its α blocking actions may cause hypotension. Low doses of droperidol have been shown to effectively reduce the incidence of postoperative nausea and vomiting when mixed with morphine and used for patient-controlled analgesia[7–9] and it has been suggested as the agent of choice for prophylaxis[10]. Newer 5-HT_3 antagonist drugs have not been shown to be significantly more effective[11] and are considerably more expensive.

Droperidol has a long duration of action and is associated with sedation and extrapyramidal reactions. When used in combination with morphine for patient-controlled analgesia, addition of droperidol appears to cause significantly greater sedation[12 13], although in single low doses it has been shown to have no effect on recovery time[14]. We were concerned that routine use of droperidol might prolong the duration of intubation after cardiac surgery. Although we did not measure sedation scores, we found that the use of droperidol had no effect on duration of postoperative intubation, nor did it prolong patient stay in the CRU. The mean dose of droperidol was approximately 5 mg during a mean stay of 21.9 h, that is approximately 0.23 mg h^{-1}. While we would not dispute that there may have been some increase in sedation which was not measured, the sedative effects were not clinically important.

In common with most other studies of vomiting, we found that both nausea and vomiting were associated significantly with female sex. Lerman[15] has suggested that the incidence of PONV is approximately 2–3 times greater in women than in men. In this study, PONV appeared to be about 1.5–2 times more common in women.

When the effect of age on the incidence of nausea and vomiting was examined, although the number of patients aged more than 80 yr was small, octogenarians suffered significantly less PONV than younger patients. At the lower end of the age range there were only three patients aged less than 40 yr but all three suffered nausea and two vomited. Thus it appears that age does have some effect on the propensity for PONV after heart surgery.

While obesity has been reported to increase PONV[4], in contrast with other studies[17], we did not show any correlation between body mass index and nausea and vomiting.

In summary, we found that the incidence of PONV after cardiac surgery was similar to that after other major surgical procedures. We also observed that the addition of droperidol to a continuous infusion of morphine significantly reduced the incidence of nausea and vomiting after cardiac surgery without prolonging the duration of intubation or postoperative intensive care stay.

Acknowledgements

We would like to thank the cardiac anaesthetic staff and the nurses of the cardiac recovery unit for their help, and Dr M.E. Sinclair for advice.

Cardiopulmonary bypass-induced changes in plasma concentrations of propofol and in auditory evoked potentials†

E. HAMMARÉN, A. YLI-HANKALA, P. H. ROSENBERG AND M. HYNYNEN

Summary

Unbound, rather than total, plasma concentrations may be related to the anaesthetic action of propofol. Therefore, we measured plasma concentrations of propofol and recorded Nb wave latencies of auditory evoked potentials (AEP) during continuous infusion of propofol in 15 patients undergoing coronary artery bypass grafting (CABG) surgery. After induction of anaesthesia with fentanyl, propofol was infused continuously at a rate of 10 mg kg^{-1} h^{-1} for 20 min, and then the rate was reduced to 3 mg kg^{-1} h^{-1}. Administration of heparin before cardiopulmonary bypass (CPB) did not affect total or unbound propofol concentration. Initiation of CPB decreased mean total propofol concentration from 2.6 to 1.7 μg ml^{-1} ($P<0.01$). Simultaneously, mean unbound propofol concentration remained at 0.06 μg ml^{-1} because of a slight increase in the mean free fraction of plasma propofol (from 2.3 to 3.5%; $P>0.05$). During hypothermic CPB, mean total propofol concentration increased to concentrations measured before bypass (to 2.1 μg ml^{-1}; $P>0.05$ *vs* value before CPB) and the mean unbound propofol concentration was at its highest (0.07 μg ml^{-1}; $P<0.05$ *vs* value before heparin). After CPB and administration of protamine, the mean total propofol concentration remained lowered (1.7 μg ml^{-1}; $P<0.05$ *vs* value before heparin) and the mean unbound propofol concentration returned to the level measured before heparin ($P<0.001$ *vs* value during hypothermia). The latency of the Nb wave from recordings of AEP increased after induction of anaesthesia, reached its maximum during hypothermia and was prolonged during the subsequent phases of the study. The latency of the Nb wave did not correlate with total or unbound propofol concentration. We conclude that the changes in total and unbound concentrations of plasma propofol were not parallel in patients undergoing CABG. During CPB or at any other time during the CABG procedure, the unbound propofol concentration did not decrease and Nb wave latency was prolonged compared with baseline values measured after induction of anaesthesia before the start of CPB. (*Br. J. Anaesth.* 1996;**77**:360–364)

Key words

Anaesthetics i.v., propofol. Heart, cardiopulmonary bypass. Brain, evoked potentials. Pharmacodynamics. Surgery, cardiovascular.

Mean total propofol concentrations of greater than 1 μg ml^{-1} in whole blood[1] and plasma[2] in conjunction with administration of opioids, have been reported to be associated with sufficient depth of anaesthesia to prevent recall of awareness in cardiac surgical patients. The measured total drug concentration may not represent adequate drug action in all circumstances and it may be important to consider also the unbound drug concentration, especially with drugs that are bound to plasma proteins to a high degree[3], such as propofol, with a bound fraction of 97–98% in healthy subjects[4]. It would be important to determine unbound plasma drug concentration in patients undergoing cardiac surgery with cardiopulmonary bypass (CPB), because in these patients there are several factors that may affect plasma concentrations and protein binding of drugs[2 5–7]. In this study, therefore, unbound and total plasma concentrations of propofol were measured during cardiac surgery in patients receiving a continuous infusion of propofol as a supplement to fentanyl-based anaesthesia. We recorded also auditory evoked potentials (AEP) and measured the latency of the Nb wave[8] as a possible indicator of anaesthetic depth, at the same times as propofol concentrations.

Patients and methods

The study was approved by the local Ethics Committee and informed consent was obtained from each patient. We studied 19 patients undergoing elective coronary artery bypass grafting (CABG) surgery. All patients had a preoperative left ventricular ejection fraction >40%. After initial inclusion, one patient was excluded because of hypotension and difficulty in weaning from extracorporeal circulation and three patients because of technical problems in the measurement of auditory evoked potentials. Thus 15 patients completed the study, but three were excluded from the AEP analyses because of electrically contaminated measurements or difficulties in identifying the Nb wave adequately at some times. The characteristics of the 15 patients are given in table 1. On the morning of operation, patients received their regular doses of β adrenergic blockers,

†Presented in part at the 11th Annual Meeting of the European Association of Cardiothoracic Anaesthesiologists, Leuven, Belgium, May 22-25, 1996 (*British Journal of Anaesthesia* 1996; 76 (Suppl. 1): A16).

calcium channel blockers and long-acting nitrates. Two hours before arrival in the operating theatre, patients were premedicated with lorazepam 60 μg kg^{-1} orally, approximated downwards to the nearest milligram.

Anaesthesia was induced with fentanyl 30 μg kg^{-1} and diazepam 0.1 mg kg^{-1} and thereafter an infusion of fentanyl was started at a rate of 0.2 μg kg^{-1} min^{-1}. Neuromuscular block was produced with pancuronium 0.1 mg kg^{-1}. After induction of anaesthesia, the trachea was intubated and the lungs ventilated mechanically with a mixture of oxygen and air ($F_{I_{O_2}}$ 0.50). After induction of anaesthesia, a continuous infusion of propofol 10 mg kg^{-1} h^{-1} was given for 20 min and thereafter the infusion rate was reduced to 3 mg kg^{-1} h^{-1} which was continued until the end of the study (5 min after administration of protamine). The infusion rates of propofol were chosen according to previous studies in patients undergoing cardiac surgery with opioid-based anaesthesia[1 2]. Ephedrine and nitroglycerin were given before and after CPB in increments of 5 mg and 100–200 μg, respectively, to maintain systolic arterial pressure at 80–150 mm Hg. The degree of neuromuscular block was estimated visually according to the train-of-four principle, using 2 Hz supramaximal stimulation of the ulnar nerve. Incremental doses of pancuronium (1–2 mg) were given to maintain block within 90–95%. Normocapnia was maintained by monitoring end-tidal carbon dioxide concentration continuously and by measuring arterial P_{CO_2} intermittently. During CPB, the lungs were ventilated to ambient air.

For CPB, we used non-pulsatile pump flow, membrane oxygenation, moderate hypothermia (nasopharyngeal temperature 30 °C) and isovolaemic haemodilution. Myocardial protection during aortic cross-clamping was achieved with cold, crystalloid potassium cardioplegia solution (Plegisol, Abbott, North Chigago, IL, USA) given anterogradely and intermittently. Systemic anticoagulation was produced with an initial dose of heparin 300 u. kg^{-1} and with subsequent additional doses of heparin to maintain blood activated clotting time (ACT) >480 s. During the cooling and rewarming phases of CPB, pump flow was 2.4 litre min^{-1} m^{-2} and during the hypothermic phase 1.8 litre min^{-1} m^{-2}. After CPB, heparin anticoagulation was neutralized with protamine sulphate 3 mg kg^{-1}.

Blood samples for measurement of plasma propofol and serum albumin concentrations and blood packed cell volume (PCV) were obtained from the radial artery into prechilled heparinized tubes at the following times: (1) after induction of anaesthesia before administration of heparin, when propofol had been infused for a mean time of 57 (95% confidence interval 48–66) min; (2) 5 min after administration of the initial dose of heparin before the start of CPB; (3) 1 min after the start of CPB; (4) during hypothermic CPB when nasopharyngeal temperature had stabilized to 30 °C; (5) after CPB before administration of protamine; and (6) 5 min after administration of protamine. The samples were centrifuged within 20 min at +4 °C at 3000 rpm for 10 min and plasma was stored at −70 °C until assayed. The unbound fraction of plasma propofol was separated by equilibrium dialysis at 37 °C, as described by Teh and colleagues[9]. The dialysis membrane was Spectra/Por, with a molecular weight cut-off of 12 000–14 000 (Spectrum Medical Industries, Inc. Houston, TX, USA). After dialysis, both plasma and buffer fractions were analysed separately for propofol concentration[4]. The detection limit was approximately 3 ng ml^{-1}. The within-day coefficient of variation of the assay of relevant concentrations was 6% or less. The unbound fraction of propofol was calculated as the ratio of unbound to total propofol concentration.

Table 1 Characteristics of the 15 patients (mean (range or 95% confidence interval) or number of patient)

Age (yr)	60 (range 43–70)
Weight (kg)	83 (75–91)
Height (cm)	171 (167–176)
Ejection fraction of left ventricle (%)	55 (49–61)
Sex (M/F)	13/2
Preoperative medication	
Long-acting nitrates	13
Calcium channel blockers	6
β adrenergic blockers	14
Aortic cross-clamp time (min)	64 (54–76)
Cardiopulmonary bypass time (min)	95 (81–110)

AUDITORY EVOKED POTENTIALS

We used the Neuropack Four Mini (Nihon Kohden, Japan) evoked potential device for acoustic stimulation and recording of evoked potentials. Rarefaction clicks of 0.1 ms and 90 dB above the normal hearing level were presented monaurally to the patient's ear via headphones at a rate of 7.0 Hz. For recording, silver–silver chloride cup electrodes were positioned at the Fz point (frontal lead) and contralateral ear lobe with an extracephalic ground. Inter-electrode impedances were maintained less than 5.0 kΩ and the amplification bandpass was set at 20–1000 Hz. Evoked potential latencies of Nb waves were measured offline, after randomization, by one of the authors (A.Y.-H.) blinded to the measurement times. The auditory responses (two averages of 500 epochs) were recorded before induction of anaesthesia and also at the same six times as the samples for measurement of propofol concentrations (see above). To exclude any impairment in hearing function, conventional air conduction audiometry at frequencies of 0.25–8 kHz was performed on the day before operation.

OTHER MEASUREMENTS

Heart rate, mean arterial pressure (MAP) and other clinical signs of depth of anaesthesia (movement, sweating, tearing), and nasopharyngeal and rectal temperatures were measured at the same times as the AEP recordings. All patients were interviewed after operation for evaluation of intraoperative awareness and recall of intraoperative events.

STATISTICAL ANALYSIS

Analysis of variance for repeated measures was used to detect significant changes in the variables over time. Analysis of covariance for repeated measures was used to define the relationship between total or unbound propofol concentrations in plasma and auditory evoked latencies and the relationship between the ratio of bound to unbound propofol concentration in plasma to blood PCV or serum albumin concentration. For subsequent multiple comparisons, Tukey's method was used[10]. $P<0.05$ was considered statistically significant. Results are expressed as mean (95% confidence intervals or range).

Results

EFFECT OF HEPARIN

Administration of heparin did not change the total plasma concentration of propofol (table 2). Simultaneously, because the mean unbound fraction of propofol increased by 53%, the mean unbound propofol concentration increased by 64%. However, these increases were not significant.

EFFECT OF CPB

Initiation of CPB decreased the total concentration of propofol ($P<0.01$ *vs* value after heparin) (table 2). Concomitantly, because the unbound fraction of propofol tended to increase, the unbound propofol concentration did not change. Compared with the value before heparin, the unbound fraction of propofol was significantly ($P<0.01$) increased 1 min after the start of CPB. During hypothermic CPB, the mean values of unbound propofol concentration and the unbound fraction of propofol were at their highest ($P<0.05$ and $P<0.01$, respectively, compared with values before heparin).

POST-CPB PHASE

After CPB, both before and after administration of protamine, total propofol concentration was lower than values before CPB ($P<0.05$ *vs* value before heparin and $P<0.01$ *vs* value after heparin) (table 2). Administration of protamine had no significant effect on either total or unbound propofol concentration. However, after administration of protamine the unbound propofol concentration was at its lowest ($P<0.001$ compared with value during hypothermic CPB). After administration of protamine, the unbound fraction had returned to baseline values, that is to the level observed before administration of heparin, and the unbound fraction was significantly ($P<0.01$) lower compared with the value during hypothermic CPB.

BLOOD PACKED CELL VOLUME AND SERUM ALBUMIN

Blood PCV and serum albumin concentration were unchanged during the period before bypass. After commencement of CPB, the values of these variables decreased significantly ($P<0.001$) and remained decreased during CPB. After CPB and administration of protamine, PCV and serum albumin concentration increased ($P<0.01$ and $P<0.05$, respectively) from values measured during hypothermic CPB, but they remained lower ($P<0.001$) than those observed before CPB (table 2). The ratio of bound to unbound propofol concentration was not related significantly to serum albumin concentration ($P=0.62$) or PCV ($P=0.23$).

NB WAVE OF THE AUDITORY EVOKED POTENTIALS

Induction of anaesthesia increased the latency of the Nb wave ($P<0.001$) and thereafter it remained prolonged until the end of the study (table 2). During the hypothermic phase of CPB, the latency of the Nb wave was increased compared with the value before the start of CPB ($P<0.05$). After CPB, the latency of the Nb wave shortened to the level measured before the start of CPB. The latency of the Nb wave was not significantly related to the total or unbound propofol concentration.

OTHER CLINICAL SIGNS

Data for other clinical signs are given in table 3. Before the start of CPB during surgery, two patients were sweating slightly (skin on the forehead moist, no visible beads of perspiration). Movement or tearing was not detected in any patient. Two patients needed increments of nitroglycerin because of hypertension before CPB. There was no recall of conscious awareness of intraoperative events reported by any patient.

Discussion

We have observed that the changes in plasma total and unbound propofol concentrations were not parallel during cardiac surgery. The most prominent differences in the changes were observed during CPB.

The decrease in total propofol concentration with initiation of CPB was probably mainly a result of the haemodiluting effect of the priming solution in the extracorporeal circuit. Binding of propofol to the extracorporeal circuit may be an additional factor in decreasing plasma concentration of propofol in patients undergoing CPB[2]. Decrease in total drug concentration with initiation of CPB has been demonstrated previously with various drugs[5,6,11], including propofol[1,2]. In spite of the decrease in total propofol concentration, we did not notice any decrease in the unbound propofol concentration when CPB was started because the free fraction of plasma propofol increased. Russell and co-workers[1] also observed a significant increase in the free fraction of plasma propofol concentration caused by CPB, but they did not report the unbound concentrations. During the later phase of CPB at 30 °C, total propofol concentration increased to pre-bypass values from values measured immediately after commencement of CPB and unbound propofol concentration was at its highest. These increases in propofol concentration may have resulted from decreases in volume of distribution and clearance of propofol during hypothermia[7]. Russell and co-workers[1] also described an "upward trend" in total propofol concentration during hypothermic CPB.

Administration of heparin tended to increase the free fraction of propofol in plasma and a reversed change was observed after protamine. Although the changes observed in this study were not significant, heparin and subsequent neutralization with protamine have been reported to affect significantly the unbound fraction of various other drugs in cardiac surgery patients[6,11,12]. Heparin activates lipoprotein lipase to hydrolyse plasma triglycerides into non-esterified fatty acids[13]. These compounds competitively inhibit the binding of various drugs to plasma proteins and may be attributed to the increase in the unbound fraction of the drug.

It has been suggested that the depth of anaesthesia can be measured with AEP during anaesthesia with various anaesthetic agents[8,14–16]. We chose to measure, among all the AEP variables, the latency of the Nb wave, which may be one of the most reliable variables to indicate the adequacy of anaesthesia, that is loss of consciousness[14,15]. In this study, the means of the latencies of the Nb wave at different recording times during anaesthesia were significantly prolonged compared with the latency while awake, suggesting an adequate level of anaesthesia. Accordingly, there was no recall of conscious awareness of intraoperative events reported by any patient. The deepest level of anaesthesia probably occurred during hypothermic CPB; at this stage Nb latency was longest and the unbound propofol concentration greatest. However, we found no correlation between the latency of Nb wave and total or unbound propofol concentration. This was probably because of simultaneous infusion of fentanyl and to some extent other confounding factors during cardiac surgery, such as hypothermia during CPB[17], altered cerebral blood flow during CPB and changes in surgical stimulation.

On-line estimation of left ventricular stroke volume using transoesophageal echocardiography and acoustic quantification

C.-A. GREIM, N. ROEWER, G. LAUX AND J. SCHULTE AM ESCH

Summary

We have examined the usefulness of transoesophageal echocardiography (TOE) and automated endocardium detection for on-line calculation of left ventricular stroke volume. In 12 of 15 patients undergoing abdominal surgery, stroke volume was derived continuously from the multiple discs (MD) and area–length (AL) methods and compared with stroke volume calculated by thermodilution. In 10 patients (80%), more than three manipulations of the ultrasound transducer were required before measurements. Linear regression analysis of automated TOE methods and thermodilution revealed weak correlations (r<0.75) for stroke volume (114 matched pairs) and its changes (105 matched pairs). Correlation of percentage changes in stroke volume calculated by thermodilution with those derived from MD (r=0.85) and AL (r=0.79) was better. Changes in MD (AL) derived stroke volume by more than 20% identified changes in thermodilution-derived stroke volume greater than 20% (n=57) with a sensitivity of 74% (70%) and a specificity of 82% (79%). Signal instability, lack of accuracy and only a moderate trend capability currently limit the intraoperative usefulness of automated TOE techniques for continuous estimation of stroke volume from a single long-axis plane. (*Br. J. Anaesth.* 1996;**77**:365–369)

Key words

Heart, myocardial function. Heart, ventricles. Measurement techniques, acoustic quantification. Monitoring, echocardiography.

Echocardiographic automated border detection (ABD), which is based on the acoustic quantification of ultrasonic back scatter signals[1], has recently been added to the intraoperative assessment of left ventricular (LV) function[2-4]. ABD algorithms have been devised to derive real-time LV volumes from single-plane long-axis views on a beat-to-beat basis. This technique uses previously established area–length (AL) or multiple disc (MD) formulae[5-6] and provides the user with digitized information on end-diastolic and end-systolic LV volume. Few transthoracic studies have investigated the potential of ABD methods for rapid on-line calculation of LV stroke volume[7-9]. This study was designed to assess the capability of ABD techniques for transoesophageal (TOE) monitoring of LV stroke volume during prolonged surgical procedures.

Patients and methods

After obtaining approval from the local Ethics Committee, we studied 15 consenting patients (aged 37–62 yr) undergoing prolonged major abdominal surgery. Measurement of cardiac output by thermodilution using a pulmonary artery catheter (7.5 F, Baxter Healthcare Corp., Irvine, CA, USA) was part of the routine anaesthetic management. All observations were made with the heart in sinus rhythm.

After induction of anaesthesia and tracheal intubation, a 5-MHz multiplane ultrasound transducer connected to an imaging system with an endocardial edge detection algorithm (Sonos 1500, Hewlett Packard, Andover, MA, USA) was introduced into the oesophagus. After a routine echocardiographic examination, the probe was positioned at the midoesophageal level and the transducer crystals rotated electronically (40–80°) until the two-chamber view with the longest LV axis was seen without imaging the LV outflow tract. This image was stored as cine loop for later reference. ABD was activated, and transmission, time-gain compensation and lateral gain control adjusted to obtain optimal back scatter imaging of the endocardium. Gain settings were maintained unchanged throughout the study. After limiting the region of interest, LV volumes at end-diastole and end-systole were calculated continuously and displayed (fig. 1) by a prototype software package integrated into the ultrasound system. The transducer was fixed at the operating table and its position corrected before each measurement of cardiac output when required to regain the reference two-chamber view. Studies were eliminated from analysis when ABD failed to detect more than 75% of the endocardial edge, compared visually with the standard two-dimensional image, or when regional wall motion abnormalities were detected. Real-time volumes were estimated from this view by two algorithms activated independently

(fig. 1). The method of discs (MD), a modification of Simpson's rule, allowed automated volume calculation from 20 equally spaced discs. The second was the area–length (AL) formula. MD and AL derived stroke volumes were calculated off-line as the difference between end-diastolic and end-systolic LV volume.

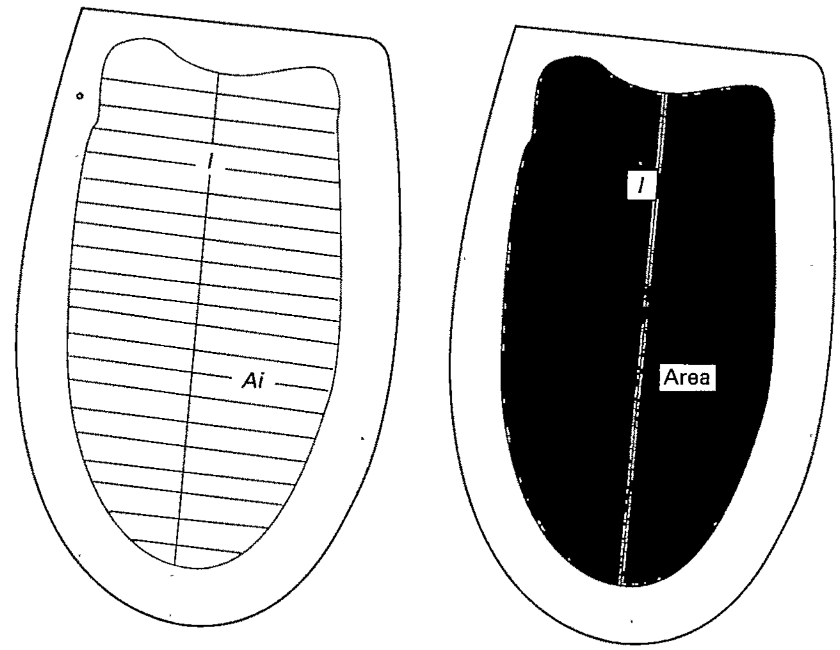
Measurements of cardiac output by thermodilution were performed in triplicate during expiration using 10 ml of iced saline. Values of 15% variation, largest to smallest, were accepted for calculating mean cardiac output and mean stroke volume as the ratio of cardiac output and heart rate. Corresponding to each thermodilution bolus, echocardiographic sequences of at least 10 cardiac cycles were recorded on videotape. During a minimum operation time of 4 h, a total of 10–14 mean cardiac output measures and serial echocardiograms were obtained for each patient. Measurements were made at intervals of approximately 15 min or at the request of the attending anaesthetist.

Videotape recordings were analysed by taking 25 consecutive cardiac cycles from each series of echocardiograms corresponding to each measurement of mean cardiac output by thermodilution. Mean values of MD and AL derived stroke volume were compared with stroke volume calculated by thermodilution by linear regression, Bland–Altman analysis[10] and analysis of variance (ANOVA). Changes in MD and AL derived stroke volume were tested for sensitivity and specificity of indicating clinically relevant changes in thermodilution stroke volume (defined as changes of more than 20%). To account for the variability in ABD determined LV volumes, we calculated 95% confidence limits of LV stroke volume, obtained from 25 consecutive cardiac cycles at each measurement. Only stroke volume data with a confidence range of less than ±20% from the mean were accepted for direct comparison with thermodilution stroke volume. Consequently, only changes in mean ABD derived stroke volume of more than 20% were considered significant.

Results

Technically adequate echocardiograms with activated ABD were obtained in 12 patients within a few minutes after insertion of the probe. Three additional patients were excluded after being entered into the study because intraoperative echocardiographic criteria were not fulfilled. In 10 patients (83%) more than three measurements required prior manipulations of the probe to correct for the pre-selected view or regain good image quality. In total, 114 corresponding measurements of ABD and thermodilution derived stroke volume (range 37–161 ml) and 105 calculations of stroke volume changes (−65–117 ml) were available for comparison; 16% of all ABD data were excluded from comparison because of unacceptable variability.

Underestimation of thermodilution stroke volume by ABD methods occurred throughout the study in all but one patient. Linear regression analysis revealed poor correlation between both ABD methods and thermodilution in determining stroke volume (r=0.66 and r=0.68). Results of Bland–Altman analysis showed a mean systematic stroke volume difference of approximately 25 ml (fig. 2), with mean estimation of cardiac output being 2.5 litre min^{-1} less than cardiac output calculated by thermodilution. No significant effects of heart rate, end-systolic or end-diastolic volume were detected between the methods. Changes in thermodilution stroke volume correlated moderately with those for



Method of discs
$V = n\pi l/4l \sum_{l=1}^{n} Ai^2$

Area–length method
$V = 8\ \text{area}^2/3\pi l$

Figure 1 Transoesophageal echocardiographic view of the left ventricle in its long axis. Left: Single-plane application of the method of discs allowed calculation of the volume of the left ventricle from 20 equally spaced discs (*Ai*, with *i*=1 to *i*=20) and the length of the long chamber axis (*l*). Right: Single-plane application of the area–length method allowed calculation of the volume of the left ventricle from the cross-sectional chamber area and long axis chamber length (*l*).

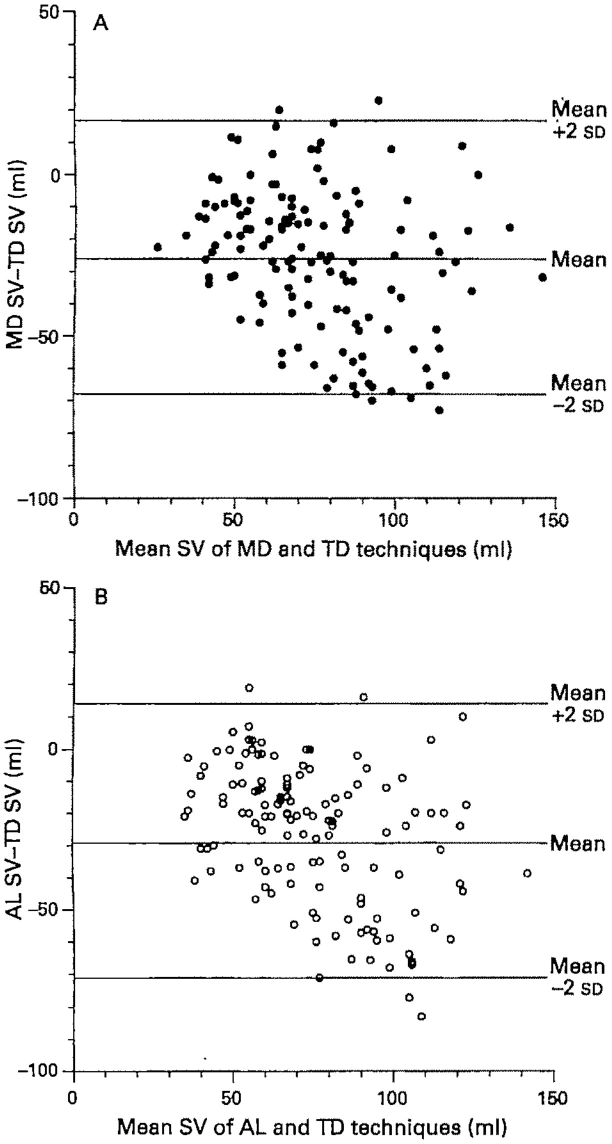


Figure 2 Bias analysis of stroke volume (SV) obtained by thermodilution (TD), and (A) the multiple disc (MD) method (mean –26 (SD 21) ml) and (B) the area–length (AL) method (–28 (22) ml).

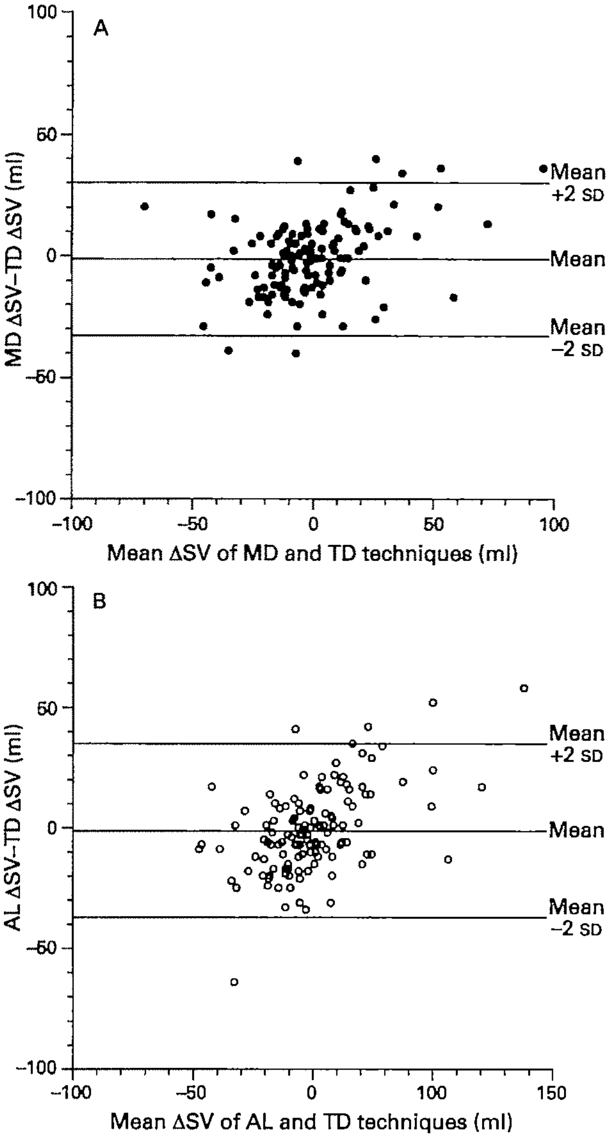

Figure 3 Bias analysis of changes in stroke volume (ΔSV) obtained by thermodilution (TD), and (A) the multiple disc (MD) method (mean –1 (SD 18) ml) and (B) the area–length (AL) method (–1 (16) ml).

MD and AL derived stroke volume (r=0.75 and r=0.69). However, Bland–Altman analysis revealed high standard deviations for both ABD methods (fig. 3). Significant good correlations between ABD methods and thermodilution were obtained for percentage changes in stroke volume (fig. 4).

Direction of changes in thermodilution stroke volume were indicated correctly in 79% (MD method) and 72% (AL method) of all measurements. Changes in MD derived stroke volume (AL stroke volume) by more than 20% identified thermodilution stroke volume changes greater than 20% (n=57) with a sensitivity of 74% (70%) and a specificity of 82% (79%). The mean positive predictive value of significant ABD derived stroke volume changes for thermodilution stroke volume changes >20% was 0.60. The mean negative predictive value of non-significant ABD derived stroke volume for thermodilution stroke volume changes <20% was 0.75.

Discussion

We have examined an advanced transoesophageal echocardiographic technique for its accuracy and trend capability in estimating LV stroke volume during abdominal surgery. With reference to thermodilution, both ABD methods had poor accuracy in determining actual stroke volume, while they correctly identified approximately 75% of changes in stroke volume greater than 20%. The technique was applicable during operation in 80% of patients. The use of the methods required frequent probe manipulations and was associated with signal instability.

There are few methods currently available for monitoring stroke volume on a beat-to-beat basis. Stroke volume is commonly derived from thermodilution, which is invasive and gives only intermittent data. In contrast, acoustic quantification analyses continuously radiofrequency data and applied to transoesophageal echocardiography has the potential to accurately measure LV cavity area[5–10]. ABD algorithms for on-line calculation of LV volumes from single long-axis views are based on formulae recommended by the American Society of Echocardiography[11 12]. Recent transthoracic studies in a canine heart model[7] and in humans[8 9] have confirmed that ABD derived stroke volume from a single long-axis plane correlates closely with stroke volume

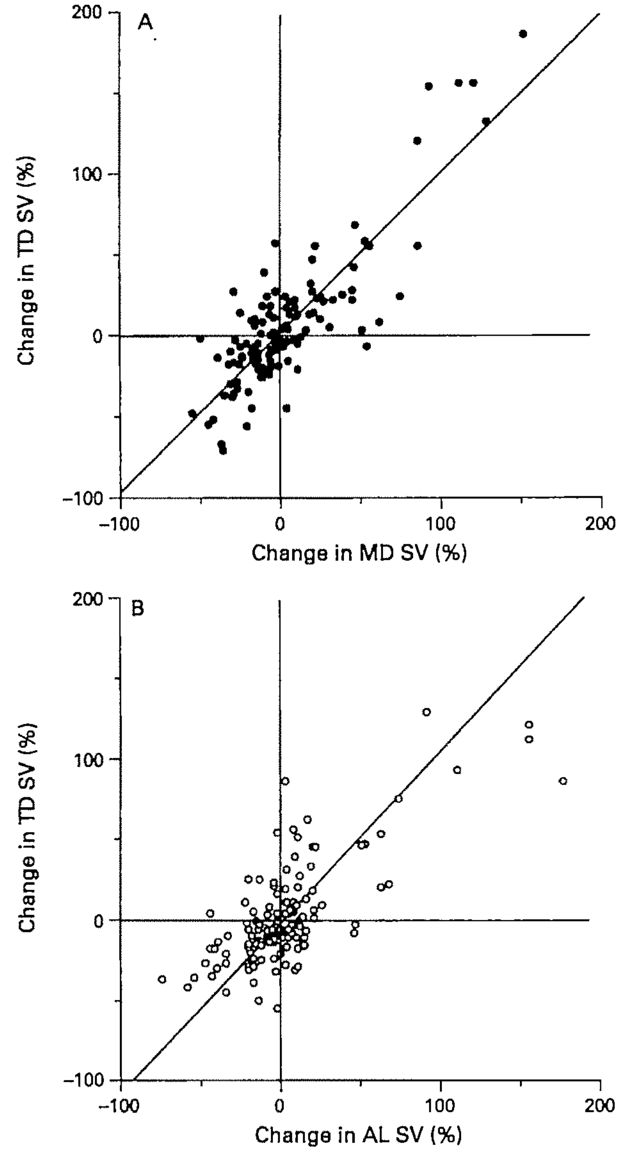

Figure 4 Linear regression of percentage changes in stroke volume (SV) obtained by (A) the multiple disc (MD) method ($y=1.0x+1.6$; $r=0.85$; SEE=32; $n=105$) and (B) the area–length (AL) method ($y=0.9x+2.0$; $r=0.79$; SEE=24; $n=105$) in relation to changes in thermodilution (TD) stroke volume.

obtained by other established methods. In common with this study, however, ABD methods consistently underestimated actual stroke volume and the limits of agreement were wide. A major drawback of this single-plane approach is the inability to see the apex of the left ventricle, which makes assessment of LV areas and axes by more than one plane a preferable technique for volume determination[13 14]. However, in the intraoperative situation, single-plane measurements provide practical advantages, because they allow rapid, serial estimates of cardiac filling and do not require data work up on various standard images.

While our results suggest that single-plane ABD methods reflect percentage changes in stroke volume and may be suitable for intraoperative trend analysis of stroke volume, they are disappointing with regard to measurement of stroke volume. Correlation of ABD methods with thermodilution showed better agreement in a previous transoesophageal study[4]. Katz and coworkers calculated regression coefficients from $r=0.74$ to $r=0.82$ for MD and AL derived stroke volume compared with thermodilution stroke volume, when a maximum of two data sets were obtained in each of 18 patients[4]. An excellent correlation between transthoracic ABD and the thermodilution technique was reported recently by Tardif and colleagues who measured cardiac output in critically ill patients[9]. In our study, the different approach and design may have contributed to the lower agreement between the ABD methods and thermodilution for several reasons. First, careful technical settings are critical to maintain precision of ABD data over hours. In our study, repeated manipulations of the probe were necessary as a result of surgical manoeuvres such as chest retraction or upper abdominal exploration. Artefacts and worsening of signal transmission with time may have occurred as a result of drying of the ultrasound transmission gel between the oesophageal mucosa and the transducer head. In addition, changes in end-diastolic LV volume required repeated adjustment of the limiting region of interest and played a role in the continuous performance of ABD methods. These factors may have contributed to the high variability in 16% of automated TOE data that required exclusion from further analysis.

Although there are several sources for ABD signal instability, we believe that a more important shortcoming of this monitoring technique is its lack of accuracy in true volume determination. This may become more prominent during major surgery involving various haemodynamic states that affect cardiac filling and contractility. Possibly, the error of a foreshortened long-axis image is potentiated by major changes in LV volume or heart rate that might result in significant variation in the selected imaging planes. Evaluation is required on the use of other single planes such as the standard four-chamber view which, in common with the two-chamber view, is reproducible and offers the potential for applying ABD methods. Another possible approach for intraoperative monitoring of stroke volume by acoustic quantification, which is based on the LV short-axis view, has been examined extensively by Gorcsan and colleagues[2 15]. This technique, however, most often requires intra-gastric positioning of the transducer probe and from our experience has a very high incidence of signal instability during abdominal surgery.

In summary, our results suggest that monitoring stroke volume with single-plane ABD methods does not hold promise as a clinically reliable technique because of the poor accuracy in computing stroke volume and signal instability, even during stable haemodynamic states, and its only moderate ability to detect acute changes in stroke volume during abdominal surgery.

Patient-controlled sedation for cataract surgery using peribulbar block

C. K. PAC-SOO, S. DEACOCK, G. LOCKWOOD, C. CARR AND J. G. WHITWAM

Summary

Patients undergoing cataract surgery using peribulbar block were allocated randomly to self-administer doses of either midazolam 0.1 mg or propofol 3.3 mg without a lock-out facility; in the control group the syringe was charged with saline, not as a placebo, but to "blind" the surgeon and the nurse observer. For midazolam and propofol, median doses were 2.54 (0.1–6.0) mg and 87.4 (0–145) mg, respectively. Patient-controlled sedation significantly reduced the level of anxiety, with median visual analogue anxiety scores in the midazolam, propofol and saline groups of 5 (0–38) mm, 5 (0–25) mm and 15 (0–92) mm, respectively ($P<0.05$). Some patients did not administer the sedative when available while others in the saline group would have benefited from anxiolytic drugs. While both drugs prevented an increase in heart rate, only midazolam prevented an increase in arterial pressure during surgery. (*Br. J. Anaesth.* 1996;**77**:370–374)

Key words

Hypnotics benzodiazepine, midazolam. Anaesthetic techniques, regional, peribulbar. Sedation, patient-controlled. Anaesthetics i.v., propofol. Surgery, ophthalmological. Age factors.

Cataract is predominantly a disease of old age[1 2]. The number of elderly patients in the UK, together with earlier referral of patients for treatment, is increasing the demand for cataract surgery[3 4], using day-care facilities[5 6].

Despite the availability of new anaesthetic drugs which allow rapid recovery, for example propofol, desflurane and sevoflurane, the use of local anaesthesia is increasing as it provides not only satisfactory operating conditions, but also advantages in terms of health economics[5]. A major disadvantage of local anaesthesia alone is anxiety, so that patients may be restless when immobility is required[7]. This may be overcome with anxiolytic drugs causing only minimal sedation. Unfortunately, a patient's response to a predetermined dose of a sedative drug may be unpredictable, particularly in the elderly where only relatively small doses are required[8–10].

An alternative would be patient-controlled sedation (PCS) which has been used successfully during surgery performed under local anaesthesia[11–14]. In early studies, the technique included an initial predetermined dose of the sedative drug before the patient took over which, by allowing the possibility of initial over sedation, may be a disadvantage. Recently, a modified patient-controlled analgesia pump (Graseby 3300, Watford, UK) without a lock-out period has been used to allow small doses of either propofol or midazolam to both initiate and maintain sedation[15]. The only restriction of access to the drug is the duration of injection of each dose, which was 5.4 s in these studies[15–17]. Patients use a much wider range of doses to achieve similar levels of psychomotor depression, with maintenance of verbal communication, than would be expected during physician administration.

We have evaluated this new method of total patient-controlled sedation in an elderly population undergoing cataract surgery during local anaesthesia.

Patients and methods

After obtaining approval from the Ethics and Research Committee (No. L94/1) and written informed consent, we enrolled 77 patients in the study. Exclusion criteria included age greater than 85 yr, clinical evidence of heart failure, severe pulmonary disease, sedative medication within the previous month, difficulty with language or communication, and poor vision in the nonoperated eye. Patients were allocated randomly to one of three groups by opening a sealed numbered enveloped containing the study group (120, 4-cm square labels, 40 each labelled midazolam, propofol, and placebo, were folded into four and mixed thoroughly in a box approximately 30 cm square by stirring and shaking, and were then taken out, placed in an envelope and numbered in the selected order). Three senior registrar anaesthetists and four ophthalmic surgeons of senior registrar or consultant status participated in the study. This was a single-blinded study with patients in the saline group informed that they were not receiving any sedation while the research nurse and the surgeons were blinded. We felt that it was inappropriate and unethical to allow patients to try to sedate themselves with saline.

*Present address for correspondence: Anaesthetic Department, Royal Postgraduate Medical School and Hammersmith Hospital, Du Cane Road, London W12 0NN.

SEDATION EQUIPMENT

The use of the sedation pump (modified Graseby 3300, Watford, UK, no lock-out, infusion rate 200 ml h^{-1}) was explained to the patients. They were told that they may not feel the need to administer any drug. If they started to feel less relaxed or anxious they should press the button as often as required until they were no longer anxious and "felt good", and while they could press the button again whenever they felt they needed more drug, they should not attempt to become unconscious. The pump contained 30 ml of one of three solutions: 0.9% saline, with or without midazolam or propofol 10 mg (1%). It was set to administer 0.33-ml aliquots of solution, that is midazolam 0.1 mg or propofol 3.3 mg. A 21-gauge cannula was inserted into a vein in the forearm on the contralateral side to the arterial pressure cuff and connected to the patient-controlled sedation pump via a primed infusion cannula (standard intravascular monitoring catheter length 150 cm, internal diameter 1 mm). Patients who were allocated to the saline group were then informed that the pump did not contain any sedative drug and that they were the control group. The number of demands, and successfully administered boluses of drugs, were recorded.

PATIENT ASSESSMENT

Sedation

The level of *sedation* was graded before performing peribulbar block by an independent "blinded" research nurse using the following scale: (1) awake, anxious; (2) awake, not anxious; (3) sedated, speech slurred; and (4) eyes closed with appropriate response to verbal command[15]. Awake patients were asked by the nurse if they felt anxious. Intraoperative assessment was made by the operating surgeon.

Anxiety

Two hours after surgery, patients were reviewed by a different anaesthetist. The level of *anxiety* experienced in the intraoperative period by the patients was assessed retrospectively using a linear visual analogue scale (VAS) from 0 to 100 mm, where 0=feeling normal and not anxious and 100=extreme anxiety.

Psychomotor test

The use of the psychomotor test equipment was explained during an initial period of familiarization. Two ascending and descending readings were obtained for critical flicker fusion, a simple response time was repeated six times and a computerized digit span memory test was also applied. The psychomotor tests were performed by a nurse trained in the use of a portable notebook computer (Compaq Contura, Compaq Computer Corporation, Singapore). Baseline tests were performed before the start of each study and repeated 10, 30, 60 and 120 min after the end of surgery. It was not possible to apply the tests satisfactorily when the treatment pathway had started, because of the speed of events, changing conditions and limited access to the patients.

MONITORING

The electrocardiogram (Cardiorecorder 364 AM, UK), heart rate and arterial oxygen saturation (Sp_{O_2}) (Novametric 515 A, USA) were monitored continuously together with intermittent measurements of non-invasive arterial pressure (Dinamap Criticon A 45, UK). Baseline readings were recorded before sedation and repeated at 5-min intervals thereafter, including the phase I recovery area after surgery.

PERIBULBAR BLOCK

All patients, whether receiving saline, sedation or those not taking sedation, indicated that they were ready for the block when assessed within 5–10 min after connection of the sedation apparatus, which in the saline group was there to blind the observers. After the research nurse had assessed the level of sedation, which took approximately 2–4 min, a peribulbar local anaesthetic block was performed on the operated eye using 8 ml of a mixture of equal volumes of 0.5% bupivacaine and 2% lignocaine to which 150 iu of hyaluronidase had been added. A Honan balloon was applied for 20 min to facilitate spread of the local anaesthetic into the muscle cone and subsequently to reduce intraocular pressure. Additional local anaesthetic was administered when required to ensure satisfactory block.

PROCEDURE

After transfer to the operating theatre, the surgical field was prepared. Oxygen was delivered at 6 litre min^{-1} by a cannula placed close to the nostrils under the drapes. The PCS apparatus was positioned near the patient's feet under the surgical drapes but easily accessible to the anaesthetist. Before surgery, the surgeon, who was blinded to the sedative technique, assessed the degree of ocular movement using a recognized scale[18].

In the intraoperative period, patients maintained their own level of anxiolysis and the anaesthetist was present throughout. The surgeon ascertained that patients were not over sedated by maintaining verbal contact. At the end of the operation, the surgeon recorded the quality of the local anaesthesia and also the patient's cooperation during surgery. Assessment of cooperation was left to the discretion of the surgeon and was considered good if the patient responded appropriately to his request and did not move unexpectedly during the procedure. Sedation was then discontinued and the duration of use of the sedation pump and surgery were recorded.

Patients were then transferred to the recovery unit (phase I) where they remained until completion of the study. After step down (phase II), patients were reviewed by a second anaesthetist before discharge.

STATISTICAL ANALYSIS

Analysis of variance (ANOVA) was applied to normally distributed data. The difference between the highest systolic and diastolic pressures and heart rate and baseline pressure in each patient were compared between groups using one-factor ANOVA. Within each group, comparison with baseline was made using Student's paired *t* tests with Bonferroni's correction. Sedation scores were compared using chi-square analysis and the median anxiety scores were compared using the Mann–Whitney *U* test. The results of the psychometric tests were analysed using

Friedman's two-way analysis of variance for repeated measurements. $P<0.05$ was considered statistically significant.

Results

Two patients were removed from the study; one became over sedated with midazolam and its effects were reversed with flumazenil 0.5 mg i.v. before the local anaesthetic block was performed; the other in the non-sedated group, suffered a posterior capsular tear with vitreous loss.

There were no significant differences in patient characteristics between the groups (table 1) and no differences in duration of surgery, quality of local anaesthesia (table 2) or ocular muscle paralysis. In one patient in the midazolam group and two in the propofol group, local anaesthetic action wore off during surgery and was supplemented with 1% topical amethocaine. Cooperation of the patients, assessed by the surgeon, was good, except for one non-sedated patient, three patients in the midazolam group and one in the propofol group (table 2).

The median total doses of midazolam and propofol were 2.54 mg and 87.4 mg, respectively (table 2). Three patients in the propofol group did not use the pump but their anxiety scores were 0–6 mm on the VAS. Three patients in the midazolam group fell asleep during surgery but were awakened immediately by verbal communication, without distress or restlessness, and with appropriate responses to instructions.

Sedation scores before performing peribulbar block were grouped as inadequate (group 1) and adequate (groups 2–4). There were significantly more patients in the saline group who were inadequately sedated compared with those in the midazolam and propofol groups (table 3). There was no significant difference in the degree of sedation between the midazolam and propofol groups and only two patients were considered retrospectively to have used too little sedation.

Overall, the non-sedated group was significantly more anxious during surgery. They had a median VAS of 15 mm compared with 5 mm in the midazolam and propofol groups (table 3). However, seven (27%) patients in the non-sedated group when assessed after surgery had a VAS anxiety score of 0 mm.

The results of the psychomotor tests, which were performed before and after the procedure, were not significantly different either between the three groups or within each group (table 4). Three patients in the midazolam group had complete amnesia for intraoperative events.

Only one patient (in the midazolam group) developed an arterial saturation of less than 90% for more than 1 min. This occurred 20 min after initiation of sedation while breathing air. Saturation improved immediately when the patient was asked to inhale a few deep breaths and remained greater than 92% throughout the remainder of the study.

There were no significant differences in mean control systolic and diastolic arterial pressures, which were 148.8 (SD 17.3) mm Hg and 86.2 (21.5) mm Hg in the placebo group, 157.5 (13.9) mm Hg and 85.7 (11.4) mm Hg in the midazolam group, and

150.1 (18.8) mm Hg and 86 (12.1) mm Hg in the propofol group. In the saline and propofol groups there were significant peak increases of 14.6 and 9.4 mm Hg in mean systolic pressure ($P<0.05$ in each). In contrast, in the midazolam group, mean arterial pressure changed by only 2.4 mm Hg (ns). In all groups arterial pressure returned to near control values by the end of the procedure. There were no significant changes in mean diastolic pressure.

One non-sedated patient was restless and his systolic and diastolic arterial pressures increased to 200 and 120 mm Hg, respectively, and were restored to normal control levels with labetalol (total dose 30 mg i.v.). The patient was not known to suffer from hypertension but was extremely anxious during surgery, with a retrospective anxiety score of 92 mm on the VAS.

Mean control heart rates were 73.2 (10.8), 72.4 (11.4) and 74.4 (11.1) beat min^{-1} in the saline, midazolam and propofol groups, respectively. There were no significant changes in heart rate throughout the study in the midazolam and propofol groups, and although the unsedated group demonstrated a significant peak increase in mean heart rate during surgery, it was only 4.2 beat min^{-1} and therefore not clinically important. Heart rate exceeded 90 beat min^{-1} in approximately 33% of patients.

Discussion

We have demonstrated that elderly patients can use patient-controlled sedation during cataract surgery to induce and maintain anxiolysis and conscious sedation with minimal drowsiness (table 3).

The term sedation used in the study dose not refer to the degree of drowsiness but rather describes a state of anxiolysis. When patients feel very relaxed, they can become very drowsy but verbal communication is retained. This method of sedation is as safe as other methods and may have advantages over other techniques where an anaesthetist or other practitioner induces and maintains sedation [7–9]. Both midazolam and propofol were effective in obtunding an increase in heart rate during surgery, which occurred in the non-sedated group, but only midazolam prevented an increase in arterial pressure, which confirms a previous report in patients undergoing cataract surgery[7].

Clearly sedation is not required in all patients undergoing cataract surgery with local anaesthesia but although the 26 patients in the control group managed without sedation, some were very anxious, as demonstrated retrospectively by the VAS anxiety scores. All patients in the midazolam group received some drug even though their median anxiety score (VAS) was only 5 mm (range 0–38 mm) (table 3). In contrast, three patients in the propofol group with VAS anxiety scores less than 6 mm did not receive any drug and seven (27%) patients in the non-sedated group had an anxiety score of 0 mm during surgery. Therefore, 10 of 75 patients (13%) did not require any sedation and for several other patients, drug consumption was minimal (table 2). Thus as the need for sedation is unpredictable and clearly there is no requirement for routine use, a case may be made for demand sedation in all patients. In these situations security and confidence are provided by patients' knowledge of the immediate availability of sedation should they become acutely anxious[15]. Moreover, intervention with sedative drugs administered i.v. by anaesthetists or surgeons can be disastrous when surgery has started. This has been demonstrated in a study where administration of infusions of either midazolam or propofol by anaesthetists during cataract surgery, to achieve a predicted level of sedation with cooperative dysarthria, caused loss of airway patency in some patients[19].

In one patient in the midazolam group, verbal communication was lost before peribulbar block was performed because of "stacking" of doses to a total of more than 5 mg. This is predictable in some elderly patients with slow circulation times. It is caused by the slow onset time of midazolam[20] and is reversed easily with flumazenil. A similar problem during cataract surgery has been reported after administration of midazolam 20 $\mu g\ kg^{-1}$ i.m. where 33% of patients fell asleep[8].

The absence of a formal lock-out time implies that the time between successful demands was only 5.4 s, that is the duration of injection of each bolus. In previous studies using the same demand sedation system in healthier younger patients, none become over sedated[15]. In this study, no patient receiving propofol, which has a shorter onset time[14,21], became over sedated. Thus although midazolam is very effective at relieving anxiety and suppressing a cardiovascular response to surgery, in elderly patients small doses and a lock-out time during patient-controlled sedation are to be recommended.

In terms of respiratory depression, our sedation technique compared favourably with other studies. For example, apnoea was reported in five (16.1%) patients who received fentanyl 0.5 μg kg^{-1} and midazolam 0.0015 mg kg^{-1} i.v.[9]. Both midazolam and propofol depress hypoxic ventilatory drive in humans[22 23] and although our method of sedation appears to be better than others[9 10], we recommend routine use of supplementary oxygen whenever possible, as the alternative of deep breathing may cause coughing.

Three (12.5%) patients in the midazolam group were completely amnesic for all surgical events. This is less than in a previous study where premedication with temazepam 10 mg orally combined with midazolam in a mean total dose 1.41 mg for cataract surgery resulted in an incidence of amnesia of 29.4%[19].

There were no significant differences in the results of the psychomotor tests before and after surgery which, on average, lasted 40 min (table 2). Because of clinical constraints, the group of psychomotor tests could not be reapplied in a valid way until the postoperative period. Patients administered only small amounts of either midazolam (median 2.54 mg) or propofol (mean 87.4 mg) (table 2), approximately 50% of the dose before peribulbar block and most of the remainder at the beginning of surgery. As the psychomotor tests were performed after the end of the procedure, that is on average more than 50 min after the last dose of either drug, it is not surprising that potential small differences between the drugs were not detected. Also, in another study where drugs were administered in predetermined doses by an anaesthetist, recovery measured by the response time was similar for both midazolam and propofol[24]. Midazolam is the recommended anxiolytic drug for use by non-anaesthetically trained practitioners[25] and has the advantage of the possibility of immediate reversibility of effect by flumazenil. Nevertheless, patients should be supervised continuously by a competent person, as has been recommended recently for propofol[26].

LABORATORY INVESTIGATIONS

Synergistic interactions between midazolam and alfentanil in isolated neonatal rat spinal cord

J. FENG AND J. J. KENDIG

Summary

Benzodiazepines, which may themselves have analgesic properties, display complex interactions with opioids. This study was designed to investigate the effects of midazolam on nociceptive neurotransmission in isolated neonatal rat spinal cord, and the interactions between midazolam and alfentanil. Slow ventral root potentials (sVRP) were recorded from a lumbar root of spinal cords isolated from 1–7-day-old rats and superfused at 27–28 °C. Midazolam (35 nmol litre^{-1} to 15 μmol litre^{-1}) significantly ($P<0.05$) depressed sVRP area in a concentration-dependent manner. Midazolam depression was antagonized by flumazenil, bicuculline and naloxone. Midazolam and alfentanil interacted synergistically, as determined by a combination index of less than 1. Midazolam blocked the rebound hyperexcitability observed when alfentanil was reversed by naloxone. The results of the study are relevant to benzodiazepine–opioid analgesia and to the effectiveness of benzodiazepines in mitigating the development of opioid tolerance and dependence. (*Br. J. Anaesth.* 1996;**77**:375–380)

Key words

Hypnotics benzodiazepine, midazolam. Analgesics opioid, alfentanil. Spinal cord. Rat. Pharmacology, synergism.

A benzodiazepine combined with an opioid analgesic is commonly used for i.v. anesthesia. There is controversy on whether or not benzodiazepines are analgesics[1–4]; given spinally, their effects appear to be analgesic[1] but systemically their sedative and anxiolytic properties may interfere with the assessment of pain[5]. Complex interactions between benzodiazepines and opioids have been reported with respect to analgesia [2 6–8], sedation–hypnosis[8–10] and development of opioid tolerance[11–13]. We have previously reported the effects of μ opioids on nociceptive neurotransmission in isolated neonatal rat spinal cord[14–16]. In response to stimulation of a lumbar dorsal root, a slow ventral root potential (sVRP) lasting 20–40 s can be recorded at the corresponding ipsilateral ventral root. The sVRP is related to nociception by several criteria. The fully developed sVRP requires C-fibre activation[17]. Both NMDA and neurokinin receptors are involved in sVRP generation[18], and both are linked to pain neurotransmission. An sVRP can be evoked by true noxious stimulation[19 20]. The sVRP is highly sensitive to analgesic agents, including opioids[14] and α_2 adrenoceptor agonists[21].

The sVRP is depressed by the benzodiazepine diazepam[22]. This study was designed to examine the effects of the benzodiazepine midazolam on the sVRP, and to investigate the interactions between midazolam and the μ opioid alfentanil.

Materials and methods

After obtaining approved from Stanford's Animal Care and Use Committee, newborn (1–6-day-old) Sprague–Dawley rat pups were anaesthetized with enflurane and decapitated. The spinal cord from the mid-thoracic to sacral level was removed rapidly and perfused at a rate of 4 ml min^{-1} with artificial cerebrospinal fluid (ACSF) at 27–28 °C, equilibrated with 95% oxygen–5% carbon dioxide, pH 7.3–7.4. This temperature is physiological for rats of this age when not in close contact with the mother. The ACSF consisted of (mmol litre^{-1}): NaCl 123, KCl 5, NaH_2PO_4 1.2, $MgSO_4$ 1.3, $NaHCO_3$ 26, $CaCl_2$ 2, glucose 30. This concentration of glucose was chosen because it increases viability in a more demanding version of this preparation, the spinal cord with brainstem attached in which spontaneous fictive respiratory discharges are maintained[23].

Suction electrodes were arranged to stimulate a lumbar dorsal root and record from the corresponding ipsilateral ventral root. Stimuli were single square wave pulses of 0.2 ms in duration. Stimulus intensity was adjusted to be supramaximal for eliciting the sVRP, and frequency was maintained at 0.02 Hz throughout the study. Responses were digitized, averaged in groups of 5 and stored for later analysis.

Controls for each experiment were the mean of 4–7 averaged responses obtained 30 min before administration of drug. Intermittently throughout the study, time-matched control experiments were carried out. Controls for individual drug experiments and time-matched controls over the duration of a typical experiment were within the range 95–105% of control means. Drugs obtained as pure compound were made up as stock solutions in distilled water,

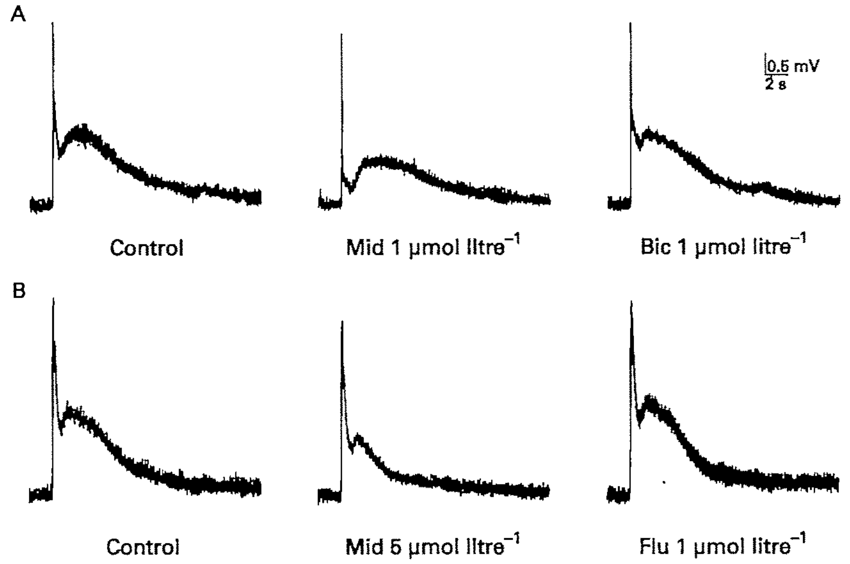

Figure 1 Examples of the effects of midazolam (Mid) on the slow ventral root potential (sVRP). A: Midazolam 1 μmol litre^{-1} depressed the sVRP and the depression was antagonized by the GABA$_A$ antagonist bicuculline (Bic) 1 μmol litre^{-1}. B: Midazolam 5 μmol litre^{-1} depressed the sVRP and the depression was antagonized by the benzodiazepine antagonist flumazenil (Flu) 1 μmol litre^{-1}.

diluted to the desired concentration in ACSF and applied to the cord in the perfusate for 30–60 min. The pH of the solution of diluted drug was 7.3–7.4. In single-drug studies, each preparation was exposed for 30 min to a single concentration of one agent, then to either drug-free ACSF or an antagonist for 1 h. In combination studies, a fixed concentration of one agent was co-administered with one of a range of concentrations of the other for 30 min; again each preparation was exposed to only one concentration of the second agent.

sVRP was quantified as the area under the curve. In a more detailed analysis, the sVRP was divided into an early area, maximally sensitive to NMDA antagonists, from 80 to 440 ms, and a late area, probably mediated via metabotropic receptors of more than one type, from 2.5 to 7.8 s[16]. Results were normalized to control. Slopes of dose–response curves were calculated by linear regression analysis of the log dose–response curve. To test for synergism against additive interactions of midazolam and alfentanil, the combination index (CI) was calculated from median-effect plots for each agent and compared with the predicted value for additivity[24].

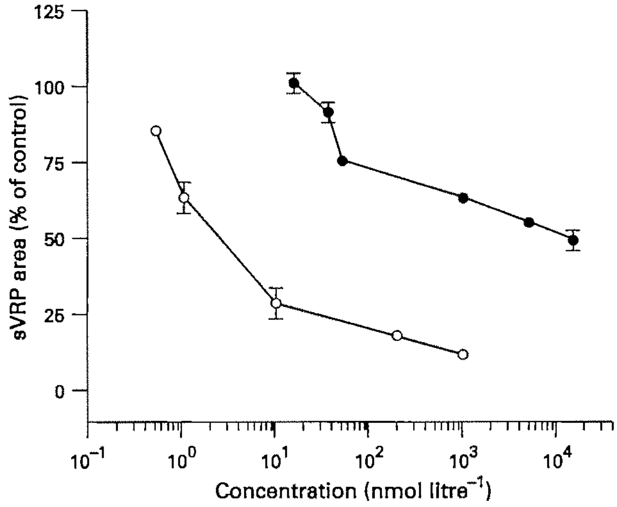

Figure 2 Dose–response curves for alfentanil (○) and midazolam (●) depression of the slow ventral root potential (sVRP). Midazolam exerted significant depressant effects at concentrations of 35 nmol litre^{-1} and above. Midazolam was less potent than alfentanil on an equimolar basis and its maximum depressant effect was much less. Data points are mean (SEM) of 4–13 experiments, in each of which the preparation was exposed to a single concentration of one of the agents.

Results

MIDAZOLAM DEPRESSION OF SVRP

Midazolam, in concentrations of 35 mmol litre^{-1} to 15 μmol litre^{-1}, significantly ($P<0.05$ to $P<0.0001$) depressed sVRP area; examples are shown in figure 1. Depression of the entire sVRP area by midazolam was concentration-dependent (fig. 2). As we have reported previously, alfentanil also depressed the sVRP area more potently than midazolam (fig. 2). Although it appeared that the slope of the midazolam concentration–response curve was shallower than that for alfentanil (midazolam slope −15.62 (SEM 2.375), alfentanil −20.92 (4.622) by linear regression analysis), the difference was not significant.

In previous studies we have shown that both μ and κ opioids selectively depressed the slower late phase of the sVRP compared with a relatively fast region sensitive to NMDA receptor antagonists[14 16]. The same was not true for midazolam. Midazolam up to 1 μmol litre^{-1} exerted similar effects on the early (80–440 ms) and late (2.5–7.8 s) phases of the response (fig. 3). At higher concentrations, however, an apparently biphasic effect of midazolam on the early phase was revealed; 5 and 15 μmol litre^{-1} continued to exert a concentration-dependent depressant effect on the late phase but appeared to be less effective than lower concentrations in depressing the early phase (fig. 3). This biphasic effect contributed to the shallow dose–response relationship for overall midazolam depression, and to the modest maximum depressant effect.

MIDAZOLAM–ALFENTANIL INTERACTIONS

Interaction between midazolam and alfentanil was examined by calculating a combination index (CI)[24]. The equation for the CI (eqn (1)) was solved in two ways: for CI using actual concentrations of agents in

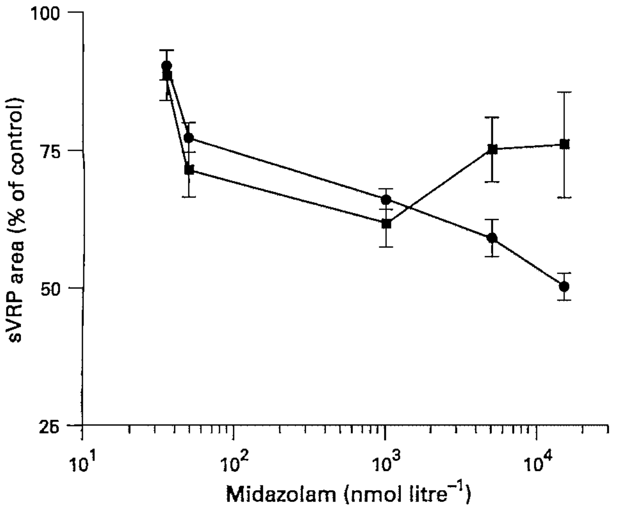

Figure 3 Effects of midazolam on the early area of the slow ventral root potential (sVRP) maximally sensitive to NMDA antagonists, 80–440 ms after the stimulus (NMDA area, ●) compared with effects on the slower metabotropic receptor-mediated component of the sVRP (late area, ●). The effects of midazolam on the two components were similar at concentrations of up to 100 nmol litre^{-1}. Above 100 nmol litre^{-1}, the effectiveness of midazolam on the early area decreased while the later area continued to decline. Data points are mean (SEM) of 5–9 experiments, in each of which the preparation was exposed to a single concentration of midazolam.

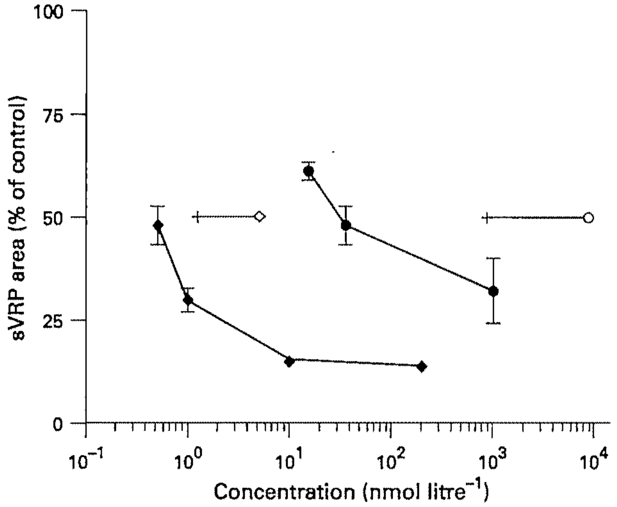

Figure 4 Concentration–effect plots determined when alfentanil was fixed at 0.5 nmol litre^{-1} and midazolam was varied (●) and when midazolam was fixed at 35 nmol litre^{-1} and alfentanil was varied (♦). These actual combinations were compared with the predicted median effective concentrations of midazolam in combination with alfentanil 0.5 nmol litre^{-1} (○) and of alfentanil in combination with midazolam 35 nmol litre^{-1} (◇), respectively, under an assumption of additivity. Data points from the actual combinations are mean (SEM) of 4–6 experiments, each preparation exposed to one mixture. Predicted concentrations were derived from equation (1) with the value for CI fixed at 1. Predicted concentrations use median effect plots derived from transformed dose–response curves. Horizontal error bars=95% confidence limits of the regression line drawn through the median effect plots. Both combinations were more effective than predicted by additivity; midazolam and alfentanil interacted synergistically to depress sVRP.

combination and the concentration of each agent required to produce a given effect by itself; and for the predicted concentration of one agent required to be added to a known concentration of the other to produce a median effect assuming additivity (CI=1). The latter was then plotted on a graph of the actual combination drug effects (fig. 4),

$$\mathrm{CI}=C_{A}/A+C_{M}/M+(C_{M}\times C_{A}/MA) \qquad (1)$$

where CI=combination index, C_A and C_M= concentrations of alfentanil and midazolam given in combination to produce a given level of effect, and A and M=concentrations of each agent separately required to produce the same level of effect. A CI value of 1 indicates additivity, less than 1 synergism and greater than 1 antagonism.

When CI was determined with known concentrations of agents to produce a given effect, values ranged from 0.1 to 0.5, depending on the effect level chosen. This result indicates that interactions between alfentanil and midazolam were synergistic. Synergism was confirmed by the finding that midazolam 15 nmol litre^{-1}, a concentration with no effect on sVRP, significantly potentiated the depressant effect of alfentanil (fig. 4). When CI was assigned a value of 1 under an assumption of additivity, and the predicted concentration of midazolam or alfentanil required to produce the median effect in combination with the other drug was calculated, the actual curves for midazolam–alfentanil combinations were shifted markedly to the left from the points predicted by the assumption of additivity (fig. 4).

RECEPTOR SPECIFICITY OF MIDAZOLAM AND ALFENTANIL ACTIONS

Midazolam is presumed to act at the benzodiazepine receptor site on the GABA$_A$ receptor. The benzodiazepine antagonist flumazenil and the GABA$_A$ antagonist bicuculline were examined for their own effects and for ability to antagonize the effects of midazolam. Both agents increased sVRP area at concentrations of 500 µmol litre^{-1} and above (fig. 5). Both flumazenil and bicuculline antagonized the effect of low (50 nmol litre^{-1}) concentrations of midazolam at concentrations at which they themselves did not increase sVRP area (50 nmol litre^{-1}); at higher midazolam concentrations (1µmol litre^{-1}), effective antagonism was observed only with higher antagonist concentrations, in the ranges in which the antagonists themselves increased sVRP area (1 µmol litre^{-1}).

There was unidirectional cross-antagonism between opioid receptor antagonist and the benzodiazepine receptor agonist. The effects of midazolam 1 µmol litre^{-1} were antagonized by the non-specific opioid antagonist naloxone at a concentration that itself had no significant effect on the sVRP (200 nmol litre^{-1}). The GABA$_A$ antagonist bicuculline (200 nmol litre^{-1}) did not antagonize the effects of alfentanil (200 nmol litre^{-1}).

MIDAZOLAM EFFECTS ON OPIOID-INDUCED HYPER-RESPONSIVENESS

We have observed previously that naloxone, given after µ opioids, precipitated an increase in sVRP area to levels above pre-drug controls[14 15]. Midazolam 35 and 1000 nmol litre^{-1}, but not 15 nmol litre^{-1} blocked this increase (fig. 6). Bicuculline 200 nmol litre^{-1} did not affect the increase, suggesting that the latter was not mediated via disinhibition at GABA$_A$ receptors (fig. 6).

Discussion

Midazolam itself depresses spinal nociceptive neurotransmission, as measured by changes in the

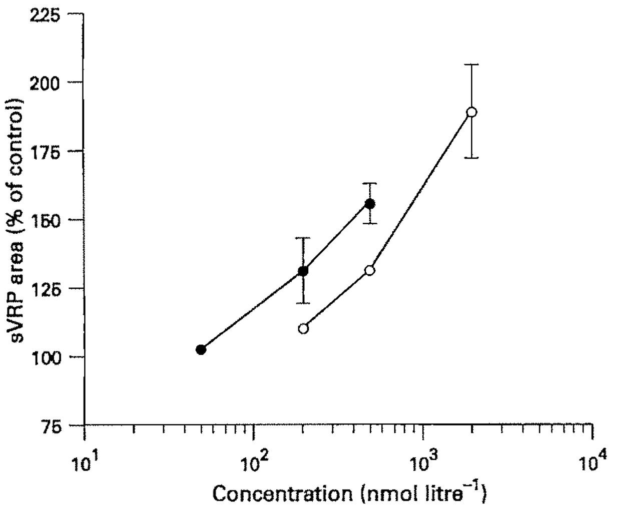

Figure 5 Both flumazenil (●) and bicuculline (○) alone increased sVRP area. The increase was significant ($P<0.05$) at concentrations of 500 nmol litre^{-1} and above for each agent. Data points are mean (SEM) of 4–6 individual experiments, each preparation exposed to a single concentration of one of the agents.

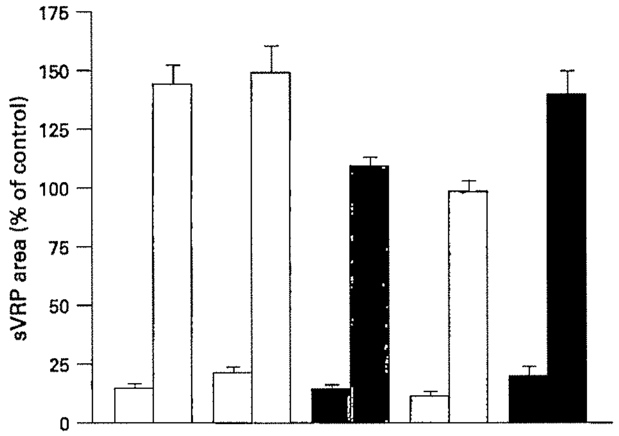

Figure 6 Midazolam prevented the rebound hyperresponsiveness observed when alfentanil 200 nmol litre^{-1} was followed by naloxone 200 nmol litre^{-1}. In each pair of bars, the agonist effect is on the left, followed by antagonist on the right. Midazolam 15 nmol litre^{-1} co-administered with alfentanil was not effective, but 35 nmol litre^{-1} and 1 μmol litre^{-1} were. Pale grey=alfentanil followed by naloxone; open bars=alfentanil and midazolam 15 nmol litre^{-1}, with and without naloxone; dark grey=alfentanil and midazolam 35 nmol litre^{1}, with and without naloxone; medium grey =alfentanil and midazolam 1 μmol litre^{-1}, with and without naloxone; solid bars=alfentanil and bicuculline 200 nmol litre^{-1}, with and without naloxone. Data are mean (SEM) of 5–14 individual experiments.

nociceptive-related slow ventral root potential. The effect, however, is complicated by a biphasic concentration–response curve for the early NMDA receptor-mediated component of the sVRP. The significance of this with respect to analgesia is unclear, although it may be related to a plateau effect and contribute to the very high midazolam doses required for immobility in response to a noxious stimulus (J. Mandema, personal communication). Its implication for midazolam–alfentanil interaction is discussed below.

In an experimental animal model of pain, flumazenil and bicuculline attenuated analgesia produced by subarachnoid administration of midazolam in the lumbar region[1]. Analgesia and a decrease in sVRP area thus result from the action of midazolam on the benzodiazepine site of a $GABA_A$ receptor population in spinal cord. Naloxone also antagonized the analgesic effect of both alfentanil and midazolam in animal models[25,26], indicating that some benzodiazepine effects may be mediated via an opioid pathway in spinal cord. GABA antagonists failed to antagonize opioid effects in animal models[1,25]. The results of our study are consistent with these findings, and suggest that the opioid receptor is downstream from the benzodiazepine receptor in the pathway. Benzodiazepines may act by enhancing release of endogenous opioids or potentiating their effects, or both. In light of marked benzodiazepine potentiation of exogenous opioid agonist effects, the latter possibility seems likely.

The effectiveness of flumazenil and bicuculline as antagonists confirms the reasonable assumption that the effects of midazolam primarily result from actions on the benzodiazepine receptor site on the $GABA_A$ receptor–ionophore. The increase in sVRP area in the presence of bicuculline alone is not surprising, as there is a marked level of tonic GABA inhibition in the isolated spinal cord, as there is glycine inhibition[27]. The increase observed with flumazenil is surprising. Flumazenil is not known to have inverse agonist effects and is considered to be a pure antagonist at the benzodiazepine site. If this is the case, then the effect of flumazenil itself on the sVRP implies an endogenous ligand at the benzodiazepine receptor.

The synergism observed between midazolam and alfentanil, the ability of naloxone to antagonize the effects of both, and the tendency of midazolam to prevent naloxone-precipitated hyperresponsiveness and the development of opioid tolerance and dependence[12,13] may share a common mechanism, at least in part. We have shown that naloxone-precipitated hyperresponsiveness after μ opioids is blocked by the non-competitive NMDA receptor antagonist MK-801[15,16]. MK-801 also potentiated the effect of morphine[16]. To account for these observations, we have proposed that μ opioids exert a long-lasting underlying excitatory effect that opposes their overwhelming depressant effect, and that is revealed when the depressant effect is abolished by the antagonist. The excitatory effect is proposed to be related to the initial steps in the development of tolerance or dependence. In common with the latter, it appears to be dependent on NMDA receptors[28–36]. It has been proposed that opioids activate protein kinase C, leading to phosphorylation of the NMDA receptor and increased activity through the latter[37].

The effect of benzodiazepines on this system may be to decrease activity through NMDA receptors, thus blocking the excitatory effects of alfentanil and apparently potentiating the opposing depressant effects. The mechanism may involve the relative hyperpolarization that occurs when currents are increased at the $GABA_A$ receptor. Magnesium block of the NMDA receptor is voltage-dependent and enhanced by hyperpolarization. Thus benzodiazepines may block NMDA receptors indirectly and reduce the excitatory effects of alfentanil. In agreement with this hypothesis, propofol, another agent which increases activity at GABA receptors, also potentiates the effect of alfentanil (Feng and

Kendig, unpublished data). Alternative hypotheses are possible, including actions of midazolam on sites other than the GABA_A receptor and a non-linear summation of the effects of enhanced GABA activity mediated via benzodiazepines and membrane hyperpolarization caused by actions of morphine on a second messenger-modulated potassium channel.

The results of this study are relevant to benzodiazepine–opioid analgesia at the spinal level and to benzodiazepine attenuation of the development of opioid tolerance. Opposing benzodiazepine effects at supraspinal levels may complicate the situation in intact animals when benzodiazepines are administered systemically. Benzodiazepines given intrathecally potentiate opioid analgesia, but given intracerebroventricularly inhibit opioid analgesia[38 39]. GABAergic agonists in periaqueductal grey and rostral ventromedial medulla may inhibit descending inhibition of spinal nociceptive neurotransmission. Benzodiazepines, which enhance GABA_A actively, may exert opposing spinal and supraspinal effects on nociceptive neurotransmission. Such opposing effects may contribute to the uncertainty regarding their analgesic properties.

Differential effects of ketamine and pentobarbitone on acetylcholine release from the rat hippocampus and striatum

K. SATO, J. WU, T. KIKUCHI, Y. WANG, I. WATANABE AND F. OKUMURA

Summary

Using microdialysis, we examined the effects of ketamine and pentobarbitone on acetylcholine (ACh) release from the rat hippocampus and striatum. Ketamine 25 and 50 mg kg^{-1} increased ACh release from the hippocampus to 295% and 353% of basal release, respectively, but not from the striatum. SCH 23390 1 µmol litre^{-1}, a D1 antagonist, significantly inhibited the facilitatory effect of ketamine 50 mg kg^{-1} on hippocampal ACh release (to 241% of basal level). In contrast, pentobarbitone 20 and 40 µmg kg^{-1} decreased basal ACh release from both the hippocampus by 41% and 69%, respectively, and the striatum by 37% and 58%, respectively. The results suggest that ketamine and pentobarbitone exert opposite effects on ACh release from the rat hippocampus and that the stimulating effect of ketamine may involve dopamine D1 receptors. (*Br. J. Anaesth.* 1996;**77**:381–384)

Key words

Anaesthetics i.v., ketamine. Acetylcholine. Hypnotics barbiturate, pentobarbitone. Brain, hippocampus. Brain, striatum. Rat.

Glutamate receptors coupled to ion channels are classified into two major groups: those that are preferentially stimulated by the agonist *N*-methyl-D-aspartate (NMDA) and those that respond preferentially to other agonists (AMPA/kainate or non-NMDA receptors)[1]. It is generally accepted that ketamine, an i.v. general anaesthetic, is a non-competitive antagonist of NMDA receptors[2–4]. Ketamine has been termed a "dissociative" anaesthetic because patients who receive ketamine alone appear to be in a cataleptic state[5]. The effects of ketamine on the gross electrical activity of the brain show marked differences from that of "depressant" anaesthetics, such as pentobarbitone[1]. Ketamine increases electrical activity in the brainstem reticular formation and limbic structures but the mechanisms are not yet fully understood.

Neurones releasing acetylcholine (ACh) are distributed widely in the brain and may be involved in memory, learning and motor functions[6]. The hippocampus receives abundant extrinsic cholinergic innervation from the medial septal area which contains choline acetyltransferase-positive neurones. The septo–hippocampal cholinergic system is considered to be under the control of dopaminergic neurones. Indeed, several studies suggest that the hippocampus is regulated by dopamine activity, primarily at dopamine-1 (D1) receptors and that D1 agonists increase ACh release in the hippocampus[7 8]. In contrast, the striatum is very important for the control of motor activity, and intrinsic neurones of the striatum are believed to be mostly GABA (gamma-aminobutyric acid)ergic and cholinergic[9 10]. The most important afferent projections appear to be the nigrostriatal dopaminergic pathway and the glutamatergic corticostriatal bundle[9 10]. We hypothesize that the differences in anaesthetic mechanisms between dissociative and depressant anaesthetics may be because of different effects on ACh release in several brain regions.

The aim of this study was to investigate the effects of ketamine and pentobarbitone on hippocampal and striatal cholinergic neurones, and also to examine the relationship between ketamine and D1 receptor mechanisms in the rat hippocampus.

Materials and methods

We used the microdialysis technique in freely moving rats. The study was approved by the Animal Welfare Committee of Yokohama City University School of Medicine. We studied 61 male, adult Sprague–Dawley rats (weighing 250–350 g), anaesthetized with sodium pentobarbitone 40 mg kg^{-1} i.p. and placed in a stereotaxic apparatus (Model SR-6, Narisige Scient Instrument Lab., Japan). The guide cannula (CMA 10, Carnegie Medicine, Sweden) for penetration of a microdialysis probe was implanted stereotaxically into the right hippocampus (coordinates obtained from the bregma with the skull flat: A: −5.6 mm, L: 5.0 mm, V: 3.8 mm from the atlas of Paxinos and Watson[11]) or the right striatum (coordinates from the bregma : A: 1.0 mm, L: 3.0 mm, V: 4 mm) and fixed in place with cranioplastic cement. After allowing at least 2 days for surgical recovery, microdialysis experiments were performed. The probe (CMA 11, Carnegie Medicine, Sweden) (3-mm long dialysis membrane, od 0.24 mm, molecular weight cut-off of 20 000 Da) was inserted into the guide cannula during light anaesthesia with diethyl ether. Microdialysis probes were perfused with Ringer's solution containing eserine sulphate 10

B: Effect of pentobarbitone (P) 20 mg kg^{-1} (○) (n=4) and 40 mg kg^{-1} (●) (n=4) i.p. on ACh release from the rat hippocampus. *P<0.05 compared with pre-drug values by ANOVA followed by Student's t test. Data are mean, SEM.

µmol litre^{-1} (Wako Pure Chemical Industries Ltd, Japan), an inhibitor of choline esterase, at 2.0 µl min^{-1}, using a microdialysis pump (Model CMA 102, Carnegie Medicine, Sweden). Implanted probes were pre-perfused with Ringer's solution for 120 min, and then every 20-min perfusate was collected in chilled polyethylene tubes containing 10 µl of ethylhomocholine 1 µmol litre^{-1}, an internal standard for HPLC measurement.

The test drugs used for these experiments were: ketamine 25–100 mg kg^{-1} i.p. (Sankyo Ltd, Japan), pentobarbitone 20–40 mg kg^{-1} i.p. (Abbott Laboratories, USA), MK-801 [(+)-5-methyl-10,11-dihydro-5H-dibenzo [a, d] cyclohepten-5,10-imine hydrogen maleate] 1 mg kg^{-1} i.p. (RBI: Research Biochemicals Incorporated, USA), a non-competitive antagonist of the NMDA receptor and non-anaesthetic agent, and SCH 23390 1 µmol litre^{-1} (local infusion) (RBI: Research Biochemical Incorporated, USA), a D1 antagonist. A new rat was used for each drug dose tested. After four collections, ketamine, pentobarbitone and MK-801 were administered i.p. SCH 23390 was added to the perfusion solution from the start of experiments and continued throughout the experiments.

ACh release was measured by HPLC-ECD using a polymeric reversed-phase column (Eicom-pak AC-GEL, 6.0×150 mm, Eicom, Japan). An AC-Enzympak column (ACh esterase and choline oxidase-immobilized, Eicom, Japan) was used to convert ACh and choline to hydrogen peroxides, which were detected (Model ECD-100, Eicom, Japan) at 450 mV. The mobile phase was phosphate buffer 100 mmol litre^{-1} (pH 8.5), containing tetramethylammonium chloride 65 mg litre^{-1} and decansulphonic acid sodium salt 200 mg litre^{-1}. The limit of sensitivity, defined as a signal-to-noise ratio >5, was 100 fmol (100 fmol/50-µl injection) for ACh and the coefficient of variation (cv) was 2.5% (n=5).

At the end of the experiments, rats were killed by overdose of diethyl ether, and the position of the probe in the brain was confirmed by visual examination. Percentage recovery of the dialysis probes was determined at the end of the experiment by dialysing a beaker containing known concentrations of ACh (here 1 µmol litre^{-1}) at 37 °C. Recovery *in vitro*=C_{out} /C_{in}, where C_{out} =concentration in the perfusate and C_{in}=concentration in the medium. Average ACh recovery through the probes at a flow rate of 2 µl min^{-1} was 16.2 (SEM 1.5) % (n=11). Basal release was obtained from the mean of four initial collections before administration of test drugs and data are expressed as percentage of basal ACh release. The significance of differences between mean values was determined by ANOVA followed by Student's t test.

Results

ACh release was stable for 120 min with baseline ACh concentrations in 20-min samples of 1.1 (SEM 0.2) pmol per sample from the hippocampus (n=39) and 6.7 (0.8) pmol per sample from the striatum (n=22).

Figure 1A and 1B show the effects of ketamine and pentobarbitone on ACh release from the hippocampus. Ketamine 25 and 50 mg kg^{-1} i.p. increased ACh release from the hippocampus in a concentration-dependent manner. The mean maximum increases in ACh release by ketamine 25 and 50 mg kg^{-1} i.p. were 295% and 353% of basal levels, respectively. Peak values of the mean increase were measured in the second sample after i.p. injection of ketamine 25 and 50 mg kg^{-1} (fraction No. 6), and ACh release declined gradually. Ketamine 100 mg kg^{-1} increased ACh release from the rat hippocampus more slowly, but ACh release remained elevated 120 min after i.p. administration (fig. 1A). There were no significant differences between the effects of ketamine 50 and 100 mg kg^{-1} i.p. in the hippocampus.

MK-801 1 mg kg $^{-1}$ i.p. significantly increased ACh release from the rat hippocampus to 338 (22.5)% (n=4) of baseline. In contrast, pentobarbitone 20 and 40 mg kg^{-1} i.p. decreased ACh release from the hippocampus in a concentration-dependent manner. Mean maximum decreases produced by pentobarbitone 20 and 40 mg kg^{-1} i.p. were 41% and 69% of basal levels, respectively (fig. 1B).

In the hippocampus, SCH 23390 1 µmol litre^{-1} (a D1 antagonist) significantly inhibited the facilitatory effect of ketamine 50 mg kg^{-1} i.p. (peak value 241% of basal levels) (n=4), while SCH 23390 1 µmol litre^{-1} alone failed to alter ACh release (fig. 2).

Figure 3A and 3B show the effects of ketamine and pentobarbitone on ACh release from the striatum. Ketamine 25, 50 and 100 mg kg^{-1} i.p. did not affect ACh release, while pentobarbitone 20 and 40 mg kg^{-1} i.p. decreased ACh release by 37% and 58% of basal levels, respectively.

Discussion

HPLC-ECD, have recently made it possible to measure various neurotransmitters in freely moving rats. This permits a precise analysis of the effects of various anaesthetic agents on neurotransmission in the various brain regions[12]. For example, previous studies indicated that diazepam reduced release of dopamine in both the nucleus accumbens and striatum of conscious rats[13], and morphine increased release of serotonin in the rat forebrain[14]. Our study examined the differential effects of ketamine and pentobarbitone on ACh release from the hippocampus and striatum using *in vivo* microdialysis combined with HPLC-ECD.

Pentobarbitone decreased ACh release from the rat hippocampus and striatum, which may suggest a powerful "depressant" anaesthetic effect of pentobarbitone. Previous studies have shown that benzodiazepine agonists decreased ACh release in the hippocampus[15] or striatum[16]. In contrast, ketamine 25–100 mg kg^{-1} i.p. increased ACh release from the rat hippocampus. Our data demonstrated that the facilitatory effect of ketamine 100 mg kg^{-1} was slower and sustained, while that of ketamine 25 or 50 mg kg^{-1} was monophasic, although the underlying mechanisms remain to be determined.

Cocaine and amphetamine have also been shown to increase ACh release from the rat hippocampus[17].

As cocaine and amphetamine are known to increase extraneuronеal concentrations of endogenous dopamine in different dopaminergic areas[17], it appears that, in the hippocampus, ketamine may have a facilitatory role in controlling dopamine release. Furthermore, it might be suggested that these opposite effects of ketamine and pentobarbitone on ACh release from the rat hippocampus underlie the different properties of dissociative and depressant anaesthetics.

ACh release from the rat hippocampus may be linked to cognitive function[17]. Cholinergic projections to the hippocampus originate from the perikarya in the medial septum and vertical limb of the diagonal band of Broca. Cholinergic activity in the hippocampus is increased during arousal, defined by behaviour or electroencephalography[8]. Increased levels of hippocampal ACh accompanied by improved memory were demonstrated. It appears that elevated hippocampal cholinergic function may improve performance of certain cognitive tasks[8]. A report that ketamine prevented the formation of flavour memories supports these findings[2]. Ketamine may have a direct effect on learning or memory storage according to our data and this may be why patients anaesthetized with ketamine experienced bad dreams. Our study does not allow a clear conclusion as to the precise mechanism through which ketamine increases ACh release from the hippocampus. However, SCH 23390, a D1 antagonist, significantly attenuated the effect of ketamine on ACh release in our study, indicating that the facilitatory effect of ketamine might involve D1 receptor mechanisms, at least in part. Day and Fibiger, and Imperato, Obinu and Gessa demonstrated that cholinergic activity in the hippocampus is increased via D1 receptor mechanisms[7,8].

In the striatum, ketamine did not affect ACh release, while pentobarbitone decreased ACh release. We have reported that ACh release from the striatum was increased via D1 receptor mechanisms and decreased via D2/D3 receptor mechanisms[18,19]. It might be suggested that ketamine has an important role in the regulation of ACh release from the rat hippocampal region, but not from the rat striatum, indicating regional selectivity between depressant anaesthetics such as pentobarbitone.

The highest density of NMDA receptors is found in the hippocampus[1]. As MK-801also increased ACh release in the hippocampus, NMDA block seems to underlie the effects of ketamine and is not simply a

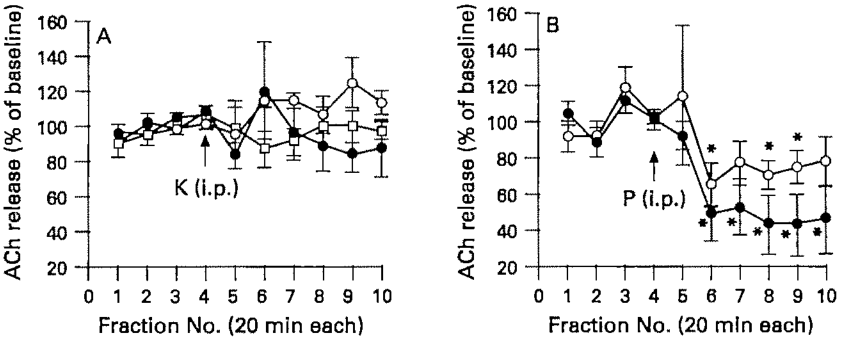

Figure 3 A: Effects of ketamine (K) 25 mg kg^{-1} (○) (n=4), 50 mg kg^{-1} (●) (n=5) and 100 mg kg^{-1} (□) (n=5) (i.p.) on acetylcholine (ACh) release from the rat striatum. B: Effects of pentobarbitone (P) 20 mg kg^{-1} (○) (n=4) and 40 mg kg^{-1} (●) (n=4) i.p. on ACh release from the rat striatum. *P<0.05 compared with pre-drug values by ANOVA followed by Student's t test. Data are mean, SEM.

result of different anaesthetic properties. However, the *in vivo* effects of NMDA receptors on the activity of cholinergic neurones in the hippocampus are still poorly understood. Recent molecular evidence showed that block of NMDA receptors increased the effects of dopamine on D1 receptors[20]. Considering these results, NMDA receptor antagonists, such as ketamine or MK-801, might be expected to increase ACh release from the rat hippocampus via D1 receptor mechanisms. Although our study of the effects of ketamine on ACh release needs further elaboration, it might help to explain the relationship between NMDA and D1 receptors in the rat hippocampus.

In summary, ketamine increased ACh release from the hippocampus, but not from the striatum, while pentobarbitone decreased ACh release from both the hippocampus and striatum. These results may underlie the differences between dissociative and depressant anaesthetics. Further, our data showed that the stimulatory effect of ketamine on ACh release from rat hippocampus may involve dopamine D1 receptors.

I.v. anaesthetic agents do not interact with the verapamil binding site on L-type voltage-sensitive Ca^{2+} channels

K. HIROTA AND D. G. LAMBERT

Summary

In this study we have examined if the i.v. anaesthetic agents thiopentone, pentobarbitone, ketamine, etomidate, propofol and alphaxalone interact with the verapamil binding site on L-type voltage-sensitive Ca^{2+} channels in rat cerebrocortical membranes. Binding assays were performed in 1 ml volumes of Tris HCl 50 mmol litre^{-1}, pH 7.4, for 90 min at 20 °C, with cerebrocortical membranes (200 µg of protein), the verapamil binding sites of which were radiolabelled with [^{3}H]verapamil. Non-specific binding was defined in the presence of verapamil 10^{-6} mol litre^{-1}. The interaction of i.v. anaesthetics was determined by displacement of [^{3}H]verapamil 0.2 nmol litre^{-1}. The mean concentrations of anaesthetic producing 25% inhibition of specific binding (corrected for the competing mass of [^{3}H]verapamil), K_{25}, were (mmol litre^{-1}): thiopentone 0.68 (SEM 0.14); pentobarbitone 1.22 (0.13); propofol 0.66 (0.10); etomidate 0.24 (0.03); alphaxalone 0.19 (0.02); and ketamine 0.75 (0.04). These concentrations exceeded those seen during anaesthesia and suggest that the neuronal verapamil binding site may not be an important target for i.v. anaesthetic agents. (*Br. J. Anaesth.* 1996;**77**:385–386)
